In the 146 cases in which the gallbladder was present, the pathological findings were predominantly those of chronic cholecystitis with superimposed elements of sub-acute or subsiding acute cholecystitis. Acute cholecystitis was reported in nine specimens.

The gallbladder was found to contain stones in 122 of the 146 cases. Review of the 24 cases in which stones were absent from the gallbladder revealed the following facts: Ten patients had previously undergone cholecys-

tostomy with removal of the stones present in the gallbladder, and in three of these patients external biliary fistulas had developed postoperatively through which any remaining stones might have escaped. Spontaneous internal biliary fistulas (cholecystoduodenal) were present in 3 of the 14 cases in which operation was not done. The calculi in the remaining cases (11) had presumably escaped into the common duct. The latter situation represents another indication for choledochotomy: a history of biliary colic or obstructive jaundice in the patient who exhibits a diseased gallbladder roentgenographically and in whom the gallbladder is found not to contain stones at operation. This indication is subject to possible exceptions by a history of previous cholecystostomy or development of internal biliary fistulas.

Noted in two cases were markedly dilated gallbladders which were exceptions to Courvoisier's well-known rule. Three patients who had undergone operation previously had remnants of a gallbladder, two of which contained stones.

6. Hicken, N. F.; McAllister, A. J.; Franz, B., and Crowder, E.: Technic, Indications and Value of Postoperative Cholangiography, *Arch. Surg.* 60: 1102-1113 (June) 1950.

Biliary fistulas were present in 18 (10.3%) of the 175 patients with stones in the common duct. These were cholecystocutaneous in four patients, all of whom had previously undergone a cholecystostomy. Cholecystenteric fistulas were present in 11, 9 to the duodenum, one to the duodenum and colon, and one to the colon alone. Eight of these were spontaneous; three followed previous cholecystostomy.

With dilated cystic duct.....	6	

* Thickening of the duct wall is probably present in a much larger percentage of cases than is noted in this series. The finding is difficult to evaluate and was not specifically recorded in many cases in which dilatation was the predominant change.

In two cases in which the previous operations included choledochotomy, fistulas later developed from the stump of the cystic duct to the skin. In the remaining case an accessory bile duct, which was presumably severed at previous cholecystectomy, acted as a safety valve for the obstructed common duct and a fistula developed from the accessory duct to the skin. This latter, isolated occurrence serves to point out the clinical importance of the extrahepatic accessory biliary ducts that were of such size and location to be noted at operation in three patients of this series, and which one of us found in 31% of a group of carefully dissected anatomic specimens.⁷

Associated pancreatitis was diagnosed at operation in 56 of the 175 patients (32%). McKittrick and Wilson noted a 10% incidence of pancreatitis in 100 cases of choledochotomy in which common duct stones were found in 52%.^{3b} The process was chronic and of moderate to low grade severity in 48 patients in our series. Those cases in which the findings were equivocal or minimal are not included. Subacute pancreatitis was present in four cases, while the process was classified as a subsiding acute pancreatitis in four others. The serum amylase level was elevated in six of these eight patients, the serum lipase was elevated in one, and moderate fat necrosis was present in the abdomen in one.

The true incidence of pancreatitis in association with choledocholithiasis is difficult to determine with accuracy. Evaluation of low-grade pancreatitis by palpation of the pancreas alone is sometimes misleading, even to the experienced surgeon. The cases in which acute pancreatitis was the outstanding feature clinically were not included in this study, as noted previously.

INDICATIONS FOR EXPLORATION OF THE COMMON DUCT

The evaluation of any single indication for exploration of the common duct is complicated by the presence of multiple indications in many cases. Table 2 presents the over-all incidence of five well-accepted indications for choledochotomy noted as significant in the 175 explorations reviewed in which abnormalities were found.

There is little disagreement regarding the first four indications, especially if more than one is present. With present-day methods the mortality resulting from cholecystectomy has not been significantly increased by the addition of choledochotomy, particularly in those cases in which the exploration of the common duct has revealed no abnormality.⁸ The factors that have caused choledochotomy to be associated with an increased mortality in the past are the prolonged presence of intermittent biliary obstruction, cholangitis, jaundice, and progressive hepatic damage plus multiple operative procedures. The increased mortality in the jaundiced patient has been noted previously.^{2d}

In order to decrease further the mortality associated with common duct stones and their removal, we must set as our goal the careful exploration of every common duct about which any suspicion of choledocholithiasis exists. It has been well demonstrated that the higher the percentage of ducts explored at the time of cholecystectomy, the greater the number of patients found to have stones in the common duct.⁹

Accepting a group of major indications such as those listed in table 2, the surgeon should not restrict his explorations of the common duct to cases in which there is only this limited group of indications. Rather, a more comprehensive understanding of the changes associated with choledocholithiasis should be realized, and the less frequent indications, which may be the only basis for suspecting the presence of common duct stones in a given case, must be given greater emphasis.

Additional indications that were present less frequently in this series were as follows: There was a history of previous cholecystectomy with recurrence of

definite symptoms in 29 patients. In 9 cases in which there had been recent, definite, biliary symptoms the gallbladder was found not to contain stones. Pancreatitis, noted on palpation of the gland, was a significant factor in four cases. A history of very frequent biliary colic was present in three cases. Persistent drainage of bile from the incision following a previous biliary operation was

Allen and Wallace.^{2a} Colcock.^{4b}

noted as a significant factor in two patients. The roentgenogram revealed stones in the region of the common duct in one patient, and the history included frequent episodes of chills and fever in one patient.

The foregoing factors were not merely incidental observations, but in most instances were noted on the operative report as significant factors in the decision to explore the common duct. Table 3 serves to stress the significance of certain of these indications in 5 of the 42 (12%) cases in which only one indication for exploration of the common duct was noted.

Table 4 summarizes the data on 70 patients in whom only two indications were noted. It should be noted how the less frequent indications acted as confirmatory factors for one of the commoner indications.

COMMENT ON INDICATIONS

The presence of stones in the common duct leads to changes of varying degree. Jaundice and dilatation of the common bile duct are primarily due to the obstruction of the flow of bile. It has been noted, however, that previous cholecystectomy or complete loss of function in the markedly fibrotic, contracted gallbladder will lead to dilatation of the common duct in many instances.¹⁰

With obstruction to the flow of bile, cholangitis often develops, causing chills and fever clinically, thickening and edema of the walls of the common duct, and further damage to the gallbladder. Cholangitis also favors further increase in the size of stones in the common duct, and is certainly a factor in the so-called re-formed stones that originate within the duct.

The relationship of pancreatitis to choledocholithiasis and cholangitis has been observed repeatedly. The relative importance of these latter conditions in the pathogenesis of pancreatitis continues to be controversial. Exploration of the common duct is felt to be indicated in cholelithiasis patients in whom pancreatitis is noted at exploration, not only to rule out and correct any obstruction at the ampulla but also to establish drainage of the common duct if the inflammatory process is marked.

Needle aspiration of bile from the common duct is a useful procedure in the evaluation of possible cholangitis.¹¹ Cloudy or turbid sediment-containing bile indicates the presence of cholangitis and obstruction, which is most commonly due to stones in cholelithiasis patients.

Cholangitis may occasionally be present in the absence of obstruction sufficient to cause dilatation of the common duct. Two such cases are represented by the last two items in table 3. A clinical diagnosis of cholangitis or the findings on aspiration of the common duct are thus important occasional indications for choledochotomy.

Indications that remain for discussion include the obvious finding of palpable stones in the common duct. Negative findings on palpation do not of course completely rule out the presence of stones, although mobilization of the duodenum will facilitate more accurate palpation of the terminal portion of the duct in the difficult case.

The presence of small stones in the gallbladder is a questionable, though occasionally helpful, indication. Buxton and Burk found stones in only one duct opened on this indication alone,¹² while stones were found in four

instances on this basis alone in our cases. Dilatation of the cystic duct or the presence of other suggestive factors strengthens this indication greatly. We had no cases in which stones were found on the basis of a contracted gallbladder alone, an experience similar to that of others.¹³

The common duct was normal on inspection and palpation in 26 choledocholithiasis patients (15%). The size of the stones removed from these ducts was reviewed in order to rule out the possibility that stones in such ducts might be small, asymptomatic, and likely to be passed into the duodenum. In only 5 of the 26 were the stones described as minute in size or stony debris; they were multiple in all cases. In 15 of the 26 there were multiple stones and in 6, single stones of average (0.5 cm.) to large size. In eight of these cases the stones were of sufficient size to be palpable but had caused no discernible changes in the duct.

The stones removed from the common duct in the entire series of 175 patients were of moderate to large size in 159 and of very small size in 16 patients. The incidence of colic and jaundice in the latter group of patients

differed from that of the series as a whole. Colic was present in 13, jaundice in only 4 patients, with both symptoms being present in only 3 of the 16 patients. Neither symptom had been present in two cases.

The operative mortality rate in 175 positive explorations of the common duct was 3.4%. Five of the six deaths occurred between 1940 and 1945. Three were primarily cardiac deaths in patients with preexistent cardiovascular disease. Glenn has also recently reported a relative increase in cardiac deaths as infection becomes less of a problem.¹⁴ Four of the patients had had previous biliary operative procedures, and four were jaundiced on admission or previously. The ages of the patients who died ranged from 41 to 80 years. The mortality was higher in men (3 in 67, or 4.5%) than in women (3 in 108, or 2.8%), as noted in previous reports.^{2d}

SUMMARY AND CONCLUSIONS

The records of 175 patients who had stones removed from the common duct by one of us (J. M. W.) are reviewed. The symptoms noted in this group included

11. Colcock.^{10b} O'Shea.^{10b} Womack and Crider.^{10b}

biliary colic in 79%, jaundice in 65%, nausea and vomiting in approximately 75%, and chills or fever or both in approximately 49%. Some degree of pancreatitis was present in 32% of the patients. The indications for exploration of the common duct are summarized for this group of patients and discussed individually. The pathogenesis and rationale of certain of the less frequent indications are stressed.

Common duct exploration should be carried out in association with cholecystectomy whenever any suspicion of the presence of stones in the common duct

arises in the form of one or more of the indications discussed. Further reduction in the mortality associated with common duct stones and their removal rests on the careful evaluation of results following choledochotomy in patients operated on for biliary tract disease or pancreatitis. Careful and thorough exploration of the common bile duct, with removal of all of the stones therein at the initial operation, would minimize the duration of changes such as obstruction, cholangitis, and progressive hepatic damage that cause secondary procedures to be associated with an increased risk.

EXPERIENCE WITH ELECTROSURGICAL OBLITERATION OF THE GALLBLADDER

Max Thorek, M.D., Chicago

In 1933 the prevailing high mortality following operations on the gallbladder in unselected cases was 9.6%. While it is true that in selected cases without complications the mortality from removal of the gallbladder in experienced hands is around 1 or 2%, a mortality of around 10% is obviously excessive. A reduction of this mortality incidence is the objective of this paper.

The postoperative complications that arise after scalpel cholecystectomy with drainage include unavoidable seepage of bile, which acts as a poison in the peritoneal cavity; thrombosis and embolism induced by bile escaping into the peritoneal cavity; erosion of blood vessels with subsequent hemorrhage; the creation of atriums for the entrance of infectious micro-organisms; and, in the older persons particularly, acute dilatation of the stomach, biliary fistulas, and pneumonia. Theoretically, when doing a classic cholecystectomy, the surgeon covers the denuded surface of the gallbladder bed with peritoneum. Unfortunately, even the most skillful and experienced surgeon cannot always accomplish this, and a large deep open wound in the gallbladder bed is often the result.

After considering this problem for some time, I concluded that leaving the posterior gallbladder wall attached to its gallbladder bed and converting the former into an inert sterile tissue tampon might be a solution to the problem. Much experimental work followed. Electrocoagulation of the posterior wall, instead of the use of a scalpel for removal of the gallbladder, and substitution of a dry nonleaking surface for the usual discharging cavity was the result. Capillaries and blood vessels of an electrocoagulated area do not thrombose; instead, a recession of the column of blood, above and below the point of contact of the electrode, takes place within the blood vessel; the vessel walls coalesce with the contiguous, homogenous, hyaline-like structures.

Since there exists some confusion and lack of distinction between the terms cauterization, electrocoagulation, fulguration, and carbonization a note of explanation is in order. The firm application of an electrode of bipolar current to a tissue surface, with a current of proper voltage and sufficient amperage permitted to pass through it, will, in a few seconds, dehydrate and coagulate the pro-

teins within that tissue and turn it white. This is electrocoagulation. If, however, this same electrode is not very firmly applied or if a unipolar or even a bipolar apparatus is used in its place, a minute air space, technically designated as a dielectricum, will intervene between the electrode and the tissue being treated. This causes sparking, with fulguration and carbonization, and cauterization is the result. The tissues will become blackened (carbonized) instead of white. If the electrode is again applied to such a carbonized tissue surface, the current will not penetrate further, so that coagulation of the underlying tissues will be impossible (fig. 1).

In cauterization, the instrument brings the heat to the tissues from the outside. In electrocoagulation, the heat is generated within the patient's body. Cauterized tissues slough. Tissues electrocoagulated inside the abdominal cavity are not thrown off or extruded as they would be from the body's external surface. Electrocoagulated surfaces within the abdomen develop "positive chemotaxis"; they attract any contiguous tissues covered with serosa (omentum, stomach, and bowels); electrocoagulated tissue becomes encapsulated and is ultimately absorbed. Firm union between the coagulated gallbladder bed and the surrounding tissues is the result.

Again, electrocoagulation of the posterior gallbladder wall and the gallbladder bed serves to prevent secondary hemorrhage because of the pressure exerted by the coagulated tissue tampon on the gallbladder bed structures. In other words, a secure sterile tampon covers the gallbladder bed, instead of the insecure open cavity that remains after classic cholecystectomy. This is the basic principle of what has now come to be known as electrosurgical obliteration of the gallbladder. During the more than two decades that have elapsed since I first reported this technique, a number of surgeons have described the use of electrosurgery in gallbladder operations. Without exception, however, their procedures have involved cauterization or fulguration, not electrocoagulation.

My aim is not to cauterize but to coagulate, to penetrate deeply, not to crust the surface. Cauterization of the gallbladder limited to the mucous membrane (the

so-called mucoclasia) does not eliminate the infected Luschka's glands of the gallbladder and chemical cauterization (carbolic acid, iodine, and so forth) is not effective. Destruction of only the mucosa by any method

Fig. 1.—Diagram showing effects of electrocoagulation and of carbonization. leaves a charred eschar that, like all eschars overlying burned surfaces, is a loosely attached foreign body, easily detached, with resulting hemorrhage, thrombosis, or

even embolism. Moreover, incomplete destruction of the gallbladder wall leaves micro-organisms dormant in the Rokitansky-Aschoff sinuses.

About 5,000 cases of electrosurgical obliteration of the gallbladder garnered from the literature and my own practice in the last 23 years showed a reduction of morbidity and mortality in unselected cases and all ages to about one-third of 1%.

TECHNIQUE

With the patient under subarachnoid block, or other suitable anesthetic, and placed in the Mayo-Robson position, a thick pad is placed between the loins, and the lower thorax and upper abdomen are elevated to the desired degree of lordosis. A large, flat, indifferent electrode is applied snugly over the patient's sacrum. A straight paramedian incision is made, extending longitudinally

Fig. 3.—*A*, redundant gallbladder portion clamped with ordinary Kocher artery forceps and removed with scissors and, *B*, cut edge of remaining portion of the gallbladder wall held in clamp and electrocoagulated (published with permission of J. B. Lippincott Company).

from the lower costal margin to the level of the umbilicus, or lower, if need be. A segment of omentum is detached and placed in a receptacle containing warm isotonic sodium chloride solution. All severed blood vessels in the omentum are carefully ligated, adjacent viscera are packed away from the operative field, and adequate exposure is assured.

After the biliary passages have been examined (surgically explored wherever indicated) for stones or other pathological conditions, the gallbladder is aspirated. The cholecystoduodenal ligament is opened, and the cystic artery and cystic duct are identified, ligated, and divided. The gallbladder contents are evacuated by aspiration into a gallbladder receptacle (fig. 2). By using ordinary straight scissors, the gallbladder is opened longitudinally, from above downward to, or even into, the upper portion of the cystic duct. One-half of the gallbladder wall is

biliary colic in 79%, jaundice in 65%, nausea and vomiting in approximately 75%, and chills or fever or both in approximately 49%. Some degree of pancreatitis was present in 32% of the patients. The indications for exploration of the common duct are summarized for this group of patients and discussed individually. The pathogenesis and rationale of certain of the less frequent indications are stressed.

Common duct exploration should be carried out in association with cholecystectomy whenever any suspicion of the presence of stones in the common duct

arises in the form of one or more of the indications discussed. About 5,000 cases of electrosurgical obliteration of the gallbladder garnered from the literature and my own practice in the last 23 years showed a reduction of morbidity and mortality in unselected cases and all ages to about one-third of 1%.

TECHNIQUE

With the patient under subarachnoid block, or other suitable anesthetic, and placed in the Mayo-Robson position, a thick pad is placed between the loins, and the lower thorax and upper abdomen are elevated to the desired degree of lordosis. A large, flat, indifferent electrode is applied snugly over the patient's sacrum. A straight paramedian incision is made, extending longitudinally

Fig. 3.—*A*, redundant gallbladder portion clamped with ordinary Kocher artery forceps and removed with scissors and *B*, cut edge of remaining portion of the gallbladder wall held in clamp and electrocoagulated (published with permission of J. B. Lippincott Company).

from the lower costal margin to the level of the umbilicus, or lower, if need be. A segment of omentum is detached and placed in a receptacle containing warm isotonic sodium chloride solution. All severed blood vessels in the omentum are carefully ligated, adjacent viscera are packed away from the operative field, and adequate exposure is assured.

After the biliary passages have been examined (surgically explored wherever indicated) for stones or other pathological conditions, the gallbladder is aspirated. The cholecystoduodenal ligament is opened, and the cystic artery and cystic duct are identified, ligated, and divided. The gallbladder contents are evacuated by aspiration into a gallbladder receptacle (fig. 2). By using ordinary straight scissors, the gallbladder is opened longitudinally from above downward to, or even into, the upper portion of the cystic duct. One-half of the gallbladder wall is

grasped with a Kocher artery forceps (straight or curved). Closing the forceps crushes the gallbladder wall and closes the blood vessels. The redundant portion of the gallbladder wall is then cut away with scissors. The procedure is repeated on the opposite side. Now only the posterior wall of the gallbladder remains attached to the gallbladder bed (fig. 3).

Fig. 4.—Electrocoagulation of posterior wall of gallbladder (published with permission of J. B. Lippincott Company).

A small electrode is now firmly applied to the exposed posterior wall of the gallbladder attached to its bed. The smaller the electrode, the quicker its action; the current will coagulate to any desired depth. The electrode should always be applied snugly to the gallbladder wall to avoid carbonization. A well-coagulated area will

Fig. 5.—Electrocoagulated edges of remaining portion of gallbladder united with interrupted sutures over which a detached portion of omentum on the falciform ligament is superimposed (published with permission of J. B. Lippincott Company).

result (fig. 4). The remaining electrocoagulated edges of the gallbladder are approximated by interrupted or continuous sutures (fig. 5). After this is done, the segment of omentum that was laid out for this purpose before the beginning of the operation is sutured over the coagulated gallbladder bed. One

suture above and one below usually suffices. An effective serous covering is thus provided for the gallbladder bed; the operated area is now securely protected against seepage (fig. 6). Satisfactory healing ensues with final encapsulation and resorption. Drainage is unnecessary and is omitted.

SUMMARY AND CONCLUSIONS

The mortality following the classic cholecystectomy in unselected cases remains high (around 10%) despite the introduction of many new surgical safeguards. In order to reduce morbidity and mortality, a method of electrocoagulation of the posterior gallbladder wall was evolved to replace the classic scalpel removal of the gallbladder. This substitutes a dry, nonleaking surface for the discharging cavity remaining after classic cholecystectomy and reduces morbidity and mortality drastically.

Fig. 6.—Free segment of omentum used to cover electrocoagulated area (published with permission of J. B. Lippincott Company).

Electrocoagulation is differentiated from fulguration, carbonization, and cauterization with which it is confused. The aim of the operation described is not to cauterize, but to coagulate, to penetrate deeply, not to crust the surface with a charred eschar, and to eliminate the diseased gallbladder tissue completely and thereby leave no foci of infection in the depth of the glands or danger from hemorrhage from incompletely closed blood vessels, leakage of bile, and open atriums for ingress of infectious matter. The present relatively high mortality following cholecystectomy in unselected cases can be greatly reduced, the morbidity curtailed, and the safety of the operation for elderly and debilitated patients much increased by employing the procedure outlined, electrocoagulation, in place of the classic scalpel technique.

POLYCYSTIC KIDNEY DISEASE AND INTRACRANIAL ANEURYSM

Eugene F. Poutasse, M.D., W. James Gardner, M.D.

and

Lawrence J. McCormack, M.D., Cleveland

Congenital anomalies are often multiple and tend to occur in certain combinations. Polycystic kidney disease is frequently found with anomalies involving other organs of the body, such as cysts of the liver or pancreas. An association reported a number of times, but not given much clinical emphasis, is that of polycystic kidney disease and aneurysm of the circle of Willis. The reports of this combination have appeared mainly as necropsy findings,¹ the patients dying either of subarachnoid hemorrhage from rupture of the aneurysm or of renal failure from polycystic kidney disease. Recognition of the combination prior to death has been unusual, but, with present roentgenologic techniques, the diagnosis can be established and definitive treatment instituted after the appearance of symptoms.

During the past two years, three patients have been seen at the Cleveland Clinic with congenital aneurysm of a cerebral artery and polycystic kidney disease. All three were relatively young and entered the hospital because of symptoms of subarachnoid hemorrhage. The first patient of the series died shortly after admission to the hospital in August, 1950, of a massive intracerebral hemorrhage. His history, although brief, is typical of the majority reported in the literature.

REPORT OF CASES

CASE 1.—A 29-year-old man experienced a severe headache behind the bridge of his nose followed by a generalized convulsion one week prior to entry. Four similar episodes occurred during the next few days, accompanied on one occasion by stiffness of his neck and vomiting. His previous health had been excellent, and there was no family history of kidney disease. Physical examination revealed a temperature of 100.5 F, pulse rate 110, respirations 25, and blood pressure 128/75 mm. Hg. At the time of entry he complained of severe headache but was amnesic concerning his illness. Nuchal rigidity was present. Shortly after admission to the hospital he had a generalized convulsion with opisthotonos. Lumbar puncture revealed bloody spinal fluid with a pressure of 350 mm. H₂O. A few hours later the patient lapsed into coma and died.

At necropsy polycystic kidneys were found, the right weighing 287 gm. and the left 247 gm. Examination of the circle of Willis showed a small "berry" aneurysm arising from the junction of the anterior communicating and left anterior cerebral arteries. The tip of the aneurysm had ruptured (fig. 1). From this point of rupture a dissecting hemorrhage passed through the right frontal lobe and basal ganglia into the right lateral ventricle and filled the ventricular system. A large zone of encephalomalacia surrounded the hematoma. The obvious symptoms of subarachnoid hemorrhage in this case suggested the diagnosis of berry aneurysm. There was no clue in his history or physical examination of congenital polycystic kidney disease.

CASE 2.—This patient, a 27-year-old man, was not known to have either anomaly prior to hospitalization, although he had had high blood pressure for several years and a family history of kidney disease. He entered the hospital in September, 1952, because of headaches and vomiting. Nine days previously a severe, generalized, throbbing headache with vomiting had suddenly developed. His physician found a blood pressure of 180/130 mm. Hg and a stiff neck. Lumbar puncture disclosed bloody spinal fluid with increased pressure. The history

revealed that in 1944, eight years prior to entry, he was rejected by his draft board because of hypertension. In recent years he had experienced several episodes of headache and vomiting, but none of the intensity that led to his hospitalization. He had no history of renal disease, but his father had died of renal disease and his only brother was known to have it.

Positive physical findings consisted of blood pressure of 210/140 mm Hg, constriction of the optic vessels, and a palpably enlarged left kidney. Urinalysis showed a trace of albumin and both red and white blood cells. The blood urea level was 21 mg. per 100 ml. A plain roentgenogram of the abdomen showed a normal right renal outline, but the left was enlarged. On intravenous urography both kidneys functioned well, and the right renal pelvis and calices appeared normal. There was elongation of all the calices of the left kidney, with some widening and distortion. It was believed that the patient had polycystic kidney disease and that the subarachnoid hemorrhage was probably from a congenital aneurysm of the circle of Willis.

Fig. 1 (case 1).—Congenital berry aneurysm of the circle of Willis arising from the junction of the anterior communicating and left anterior cerebral artery. An asterisk marks the neck of the sac. The inset shows the sac and point of rupture.

Retrograde pyelograms confirmed the previous findings in the left kidney and also demonstrated suggestive changes of polycystic disease in the right kidney (fig. 2). A few hours after cystoscopy the patient suddenly became unconscious, and no blood pressure was obtainable. He had dilated fixed pupils, respiratory failure, and bilateral Babinski responses. Artificial respiration was started, and the blood pressure was supported with phenylephrine (Neo-Synephrine) hydrochloride infusion. Lumbar puncture revealed clear fluid with a pressure of 110 mm. H₂O. Immediate, bilateral, internal carotid arteriograms were carried out, but the dye did not pass beyond the level of the sella turcica. Exploratory trephination was performed, and a hematoma was evacuated from the right frontal lobe. The patient's condition did not improve, and life was maintained for only a few hours by the respirator.

At necropsy bilateral polycystic kidneys were found, the left being twice the size of the right (fig. 3). A congenital aneurysm

Potts Educational Institute, Cleveland, H. S. Association of Diseases of Kidneys and Aneurysms of Cerebral Arteries. *J. Surg.* 42: 3-9 (Sept.) 1939.

of the right middle cerebral artery had ruptured; the resulting hemorrhage had dissected through the cerebral substance into the right lateral ventricle. Focal necrosis of the pons and mid-brain was present. Histological sections of the aneurysm showed the wall to be of variable thickness and composed of fibrous tissue only. A focus of necrosis was present at the site of rupture.

Fig. 2 (case 2).—Retrograde pyelogram showing enlargement of left kidney with elongation, widening, and distortion of all calices. Right kidney shows only minimal roentgenographic changes.

CASE 3.—This patient, a 40-year-old woman, was known to have symptomatic polycystic renal disease for one year before symptoms of the intracranial aneurysm appeared. She was seen in July, 1951, with gross hematuria, right flank pain, and fever. There was no family history of kidney disease. On examination her blood pressure was 130/65 mm. Hg, and large tender masses were felt in both flanks. The urine contained many red and white blood cells, but culture was sterile. The blood urea was 24 mg. per 100 ml. Roentgenographic studies showed enlarged renal outlines, with elongation and distortion of all calices characteristic of polycystic kidney disease (fig. 4). Translumbar aortography demonstrated distortion of the renal arterial system corresponding to the caliceal distortion. With bed rest and antibiotics she recovered from the bleeding and infection and returned to her home.

A year later she experienced sudden, severe, transient headache associated with stiffness of the neck. Two weeks later she had a generalized convulsion followed by right hemiparesis and aphasia. On this occasion, a lumbar puncture disclosed bloody spinal fluid under high pressure. On arrival at the hospital she was found to have a stiff neck, right hemiparesis, and a dilated right pupil. The blood pressure was 130/95 mm. Hg; the blood urea level was 24 mg. per 100 ml., and the urine contained only

a few white blood cells. Three days after entry a sudden headache developed, with temporary respiratory arrest and coma. A week later a left carotid arteriogram showed a small aneurysm on the medial aspect of the internal carotid artery just below its bifurcation. There was dislocation of the anterior cerebral artery indicating an intracerebral clot (fig. 5). With the patient under thiopental (Pentothal) and hypotensive spinal anesthesia, a left frontal craniotomy was performed and a hematoma was aspirated from deep within the frontal lobe. The aneurysm was found lying on the optic nerve. A silver clip was placed across the base of the aneurysm, leaving the cerebral circulation intact.

The patient gradually regained her speech and use of her right side, but partial amnesia for the two year period prior to operation was still present one year later. Although she has polycystic kidneys, their function is apparently adequate to maintain good health, as her blood urea level has remained normal and the urea clearance test shows 75% of normal function. Because of the abundance of symptoms, signs, and roentgenographic findings, it was not difficult to establish a diagnosis of polycystic kidney disease and congenital aneurysm in this patient.

COMMENT

The majority of intracranial aneurysms are believed to be of congenital origin and are distinctly saccular in shape.² They are known as "berry" aneurysms because of their shape and smooth, dark coats.³ They most frequently appear at or near the bifurcation of the larger cerebral arteries, occurring four times as often in the anterior half as in the posterior half of the circle of Willis. Congenital aneurysms are usually single but may be multiple. The origin of these berry aneurysms is not definitely known; they may develop because of congenital defects of the media, with thinning out of the elastica,⁴ or because of persistent remnants of the embryonic capillary network.⁵ The former mechanism is favored. The arteriosclerotic aneurysm is much less common and

is usually a fusiform dilatation of one of the major vessels of the circle of Willis.⁶ Various degrees of arteriosclerosis are usually evident in its walls.

Polycystic kidney disease is known to be congenital in origin and consists of an extensive involvement of the parenchyma of both kidneys by cysts of varying sizes. It can be recognized in newborn infants, but it usually be-

comes evident in the middle decades. There is a definite tendency for this malformation to be familial, although isolated cases may appear. This familial tendency is of diagnostic aid. An excellent description of both the infantile and the adult type is presented by Lambert.⁷

In 1951, Brown⁸ summarized the previous reports of patients who had the combination of polycystic kidneys and intracranial aneurysm; to these he added seven other patients, one of whom was suspected of having the coexisting anomalies before death. In 11,245 autopsies, he found 36 cases (0.32%) of polycystic kidneys and 148 cases (1.3%) of cerebral aneurysms. Six patients were discovered to have both anomalies, the relationship being present in 4% of cases of intracranial aneurysm and in 16.6% of cases of polycystic kidney disease. These six patients died of subarachnoid hemorrhage from or associated with aneurysms. Unfortunately, the brain was examined in only 16 of the 36 patients with polycystic kidneys. Brown concluded that the two anomalies are associated more frequently than would occur by chance. He believed the two anomalies have a common etiology and are of congenital origin. Two earlier reports are also pertinent. Suter⁹ in 1949 reviewed 5,960 autopsies and found 23 cases of ruptured congenital aneurysm and 4 that were unruptured. In the same series were five cases of polycystic kidney disease, and two of these patients had died of ruptured intracranial aneurysm. Sahs¹⁰ in 1950 reported 60 cases of intracranial aneurysms verified by necropsy and found 4 instances of associated polycystic kidneys.

Since Brown's report, Hamby^{2b} reviewed his experience with 86 patients who had proved aneurysms, 3 of whom had polycystic kidneys. Bigelow¹¹ also describes three patients who had the combination of anomalies. The reported total of patients in whom these anomalies are known or probably coexist is 44, to which

Fig. 4 (case 3).—A, enlarged renal outlines with elongation, widening, and distortion of all calices characteristic of polycystic kidney disease. B, translumbar aortogram. Note that arterial system spreads out evenly over each kidney.

we are adding 3. One of our patients is the first with this combination of conditions to have undergone successful surgical correction of the aneurysm. Bigelow presents statistics from the Albany Hospital that compare closely with those of Brown. In 8,892 necropsies, 47 cases of congenital berry aneurysm were found, in 3 of which polycystic kidneys were also found (6.4%).

Three patients of 18 with polycystic kidneys had intracranial aneurysms (16.6%).

It is noteworthy that most of these reports indicate that the patients with the combined anomalies die from rupture of the intracranial aneurysm and that the polycystic kidney disease is frequently an incidental finding

Fig. 5 (case 3).—Cerebral angiogram showing small aneurysm arising from the medial aspect of internal carotid artery below its bifurcation. The anterior cerebral artery is pushed beyond midline indicating an associated intracerebral hematoma.

at autopsy. Relatively few died of renal failure with an unruptured congenital aneurysm being found at examination of the brain. In Brown's report, 8 (22.4%) of the 36 patients with polycystic kidneys died of subarachnoid hemorrhage. Bell,¹² on the other hand, states that the incidence of cerebral hemorrhage in patients with polycystic kidney disease is so low that it may be regarded as an independent disease. At the Cleveland Clinic¹³ there have been 94 patients with polycystic kidney disease, 15 of whom are known to have died. The majority of the fatalities were caused by renal failure. Five have come to necropsy here: two of these died of hemorrhage from ruptured intracranial aneurysm; one died of renal failure and was found to have a fusiform dilatation of the junction between right anterior artery and anterior communicating artery; and two others died presumably of renal failure, but permission for examination of the brain was not granted.

It is interesting to compare the relationship of intracranial aneurysm to polycystic disease and coarctation of the aorta. The incidence of polycystic renal disease from combined autopsy statistics reported by Bell¹² is 1 in 351. The incidence of coarctation of the aorta from autopsy records as reported by Reifenstein¹⁴ is 1 in 3,000; of 104 cases of coarctation of the aorta, 5 (4.8%) had ruptured intracranial aneurysm. Wright¹⁵ collected 304 cases of coarctation of the aorta and found that 16 had intracranial aneurysm (5.2%). The association of polycystic kidneys with berry aneurysm appears to be commoner (16%) on the basis of autopsy series previously mentioned.

SUMMARY AND CONCLUSIONS

Three patients with the combination of congenital intracranial aneurysm and polycystic kidneys are reported on, making a total of 47 such cases in the literature. The association of these two congenital anomalies appears to be commoner than is generally realized. One of our patients (case 3) with the combination of anomalies, in whom the diagnosis of bleeding intracranial aneurysm was established, successfully underwent surgical correction of the aneurysm. Patients known to have polycystic kidneys who manifest migraine headache or symptoms of cerebrovascular accident should be promptly investigated if intracranial aneurysms are to be discovered in time to offer a chance for survival from hemorrhage. This is especially true in those who have a favorable life expectancy in terms of renal reserve.

The General Practitioner and Mental Hygiene.—There are influences bearing upon every individual as he grows and develops, probably most significantly during infancy and childhood, though personality maturation does not cease at adolescence. The practitioner and the health officer will need to be concerned, both in the treatment and the prevention of personality disorders, with cultural pressures on the individual, both as felt in the community and as transmitted from generation to generation. The material used in personality structure is not complicated—it consists of the homely things of everyday life and of the individual's reactions to them. There is much still to be understood about how that marvel of complexity yet efficiency, the human nervous system, combines and integrates experiences, but it does so by conscious and unconscious memories that make the personality of the moment interpretable in terms of past experiences. In the diagnosis and treatment of patients who have functional disorders, with or without organic disease, these building stones of personality will have to be examined, the data being obtained from the original and exclusive source—the patient. Prevention of many personality disorders will consist in attempts to insure the maintenance of healthy, appreciative attitudes between children and their parents and those who stand *in loco parentis* from time to time. Dealing with these matters enhances the satisfaction of the practitioner and can result in the alleviation of psychiatric symptoms. In the prevention of personality breakdown, P. J. P. CLINICAL NOTES

USE OF HYALURONIDASE TO PREVENT URINARY CALCULI

REPORT OF A CASE IN WHICH STONE RECURRENCE WAS FACILITATED BY HYALURONIDASE THERAPY

Edwin L. Prien, M.D., Brookline, Mass.

In 1951 Butt¹ reported clearance of turbidity of the urine of persons predisposed to calculus formation after the subcutaneous injection of the enzyme hyaluronidase. In 1952 the same author,² in association with Hauser and Seifter, published further studies on the mechanism of this phenomenon and also reported its use in the prevention of recurrence of urinary calculi. It was stated that the subcutaneous injection of hyaluronidase results in the release of hyaluronic acid from the subcutaneous connective tissues and its excretion in the urine in a degraded or hydrolyzed form in which the individual particles act as protective colloids. The protective colloid "not only disperses crystalline matter already present but also inhibits the formation and growth of new crystalline matter."²

The importance of the urinary colloids in increasing the solubility of the stone-forming crystalloids has been debated for many years. What the proponents of the colloid theory were able to prove to make their point was quite as convincingly disproved by those who believed that colloids had nothing to do with the matter. Most of the recent workers have concentrated their efforts on the urinary crystalloids in their efforts to prevent stone formation in the urinary tract. The discovery of Butt has shifted attention to the colloids rather than the crystalloids as possible important factors in stone formation and prevention.

The originality of Butt's observation, its apparent plausibility, and the enthusiastic nature of the early clinical reports have resulted in considerable interest among physicians. A glowing and inaccurate report by two staff writers of a popular lay magazine with a very large circulation caught the public eye this past winter, so that patients in whom stones form have been demanding hyaluronidase therapy. Since such therapy involves a preparation (hyaluronidase) that physicians have been using with almost complete impunity to facilitate the spreading and absorption of hypodermoclysis fluids, it is obvious that physicians should be willing to try hyaluronidase for stone prevention without too much consideration, either for its safety or its efficacy. To date I know of no published reports on hyaluronidase therapy for renal calculus except those of Butt and his co-workers.

This paper is the result of an 18 months' study of the effect of hyaluronidase on the stone-forming crystalloids, both on the basic science and clinical levels, and includes the report of an unfortunate complication resulting from such therapy. The study is consequent on a previous study³ of the crystals of urinary sediments and urinary calculi and of the stone-forming process, in which the structure and composition of calculi, from the standpoint of crystallography, were correlated with the clinical history of patients from whom stone had been obtained. It seems logical to evaluate the effects of hyaluronidase on the previously determined characteristic crystal morphology and related phenomena of the stone-forming process after subcutaneous injection of the enzyme in patients predisposed to calculus formation and in normal persons.

Briefly stated, Butt and associates have found that subcutaneously administered hyaluronidase, mixed with isotonic sodium chloride clears the turbid urine of patients in whom calculi form of sediment for periods of time varying from 24 to 72 hours. It should be stated that the concern here is with the turbidity due to the stone-forming salts only. Turbidity due to blood, pus, bacteria, albumin, and sperm would not be cleared by hyaluronidase, and the presence of these elements may render the test useless. The dosage of the enzyme used varies from 150 turbidity reducing units (TRU) upward, with doses up to 900 TRU or more daily in some cases, depending on how long the urine will be kept free of turbidity by a single dose. For determination of the proper dosage schedule, patients are required to pass specimens of urine at intervals of 1, 2, 4, 8, 16, and 24 hours after injection of a single dose (usually 150 or 300 TRU) and the duration of the clearing effect is noted. When the enzyme is used therapeutically, another dose is given at the proper time interval to keep the urine clear and free of sediment continuously. Complete details of the procedure are contained in the article in *THE JOURNAL*.² Butt has reported that hyaluronidase therapy has been effective in preventing calculus formation during a period of 11 to 21 months in 19 of 24 patients, in whom kidney stones had previously formed at a rapid rate. He has stated that his best results have been obtained in patients with multiple, rapidly recurring calyceal calculi. This type of stone lesion is commonly found in patients in his section of Florida; it is not the commonest stone lesion in patients in the northern part of the United States, however.

In my studies I have found that there is marked variation in the clearing effect on turbid urine after subcutaneous injection of hyaluronidase. Many patients have no clearing at all, and in others it lasts for only a few hours. Usually it lasts from 4 to 12 hours only. In the turbid urines of patients with urea-splitting infection very large dosages may be necessary to produce clearing, as high as 1,500 units twice daily. Often even this dosage fails to clear the urine.⁴

The fundamentals of the action of this enzyme on the urinary crystalloids have been studied optically by a technique devised by Hauser.² Thin films of urine dried on scrupulously clean glass slides are made from the voided urine before injection of the enzyme and at stated intervals after injection until the effect (if any) of the

enzyme has disappeared. The slides are then examined on a special dark-field microscope, called an Ultropak, in which the light comes down from above (instead of up from below as in the conventional dark-field microscope). The effect seen microscopically does not always parallel the gross clearing effect.

SENSITIZATION REACTION

In certain cases (fortunately few) the aggregation of crystals is enhanced and stone formation facilitated by the enzyme. This reaction is known as sensitization in colloid chemistry. The enhanced aggregation of crystals in these cases is said to be due to too small a dose of hyaluronidase. In June, 1952, I saw a patient in consultation in whom this unfortunate mechanism apparently occurred, resulting in loss of a kidney. After a small cystine stone was removed from his left kidney, the 30-year-old white man was given an injection of 150 TRU of hyaluronidase (the contents of one ampul) daily for 10 days, thereafter on alternate days for two months. In addition to the enzyme he also received enough sodium bicarbonate daily to keep his urine alkali-

Fig. 1.—A, roentgenogram of the abdomen, showing opaque calculus that fills the pelvis of the left kidney. B, intravenous urogram, several days later, showing good excretion of contrast medium by both kidneys. The left renal pelvis is still occupied by the calculus.

line; this increased the solubility of the cystine and should have retarded stone formation. At the end of the two months' period a roentgenogram of the abdomen was taken, and it showed a calculus of moderate density that filled the pelvis of the left kidney. Intravenous pyelography showed good function of this kidney with the evidence of normal appearing calyces that were filled with the contrast medium (fig. 1). At this time the patient was referred to me, and I thought that the recurrent stone was of calcium phosphate, because it was quite radio-paque and because the patient had been given alkali therapy.

Ultropak microscope studies of urinary films on slides showed the typical sensitization reaction of the enzyme in a dose of 150 TRU. There was no gross clearing effect of the urine with doses up to 600 TRU; the study was

3. Prien, E. L., and Wyeth, J. C. *Uroliths*. I. The Composition of Urinary Calculi. *J. Urol.* 57: 949-953 (June) 1947. Prien, E. L. Studies in the Pathogenesis, Structure and Composition of Urinary Calculi. *J. Urol.* 61: 321-336 (May) 1949. 4. The hyaluronidase study was Wyeth and Co., Inc.

not carried further. The slide in figure 2 shows the typical aggregation of needle-like crystals in sunbursts and in sheaf-like clusters.

A study of the two cystine stones was very illuminating (fig. 3). The first stone, removed before hyaluronidase therapy was instituted, showed the typical cystine stone structure; it was composed of a loose aggregation of typical hexagonal plate-like crystals. The stone, formed during hyaluronidase therapy and removed by

Fig. 2.—Film of urine, dried on glass slide, demonstrating sensitization reaction. Needle-like crystals of cystine in "sunburst" aggregations. Ultropak microscope ($\times 55$) was used.

nephrectomy, completely filled the kidney pelvis and was extremely dense and hard. It was this extreme density that produced the considerable x-ray density in the roentgenogram of the abdomen. (Ordinarily cystine calculi are only slightly radiopaque.) The stone was composed of closely packed microscopic needle-like crystals (spherulites). This type of structure was also seen in the urinary films on the glass slides studied under the Ultropak microscope when the sensitization reaction was manifested. Such a spherulitic growth is commonplace in the field of crystallography and represents an abnormal type of crystallization, produced, in general, by the action of a foreign material added to or present in the crystallizing solution that interferes with the development of the growing crystals. It should be stated that when chemical compounds are allowed to crystallize normally from solution the crystals of each compound assume a definite geometric form characteristic for that compound. This normal crystal form (hexagonal plates) was present in the first calculus only. Absence of such crystals in the second calculus ruled out the possibility that part of the first calculus was allowed to remain in the kidney to serve as a nucleus for the second stone. A personal study of cystine calculi from 158 patients showed no calculi with a similar spherulitic structure. Under the circumstances it seems reasonable to conclude that hyaluronidase may have been responsible for the formation of this large cystine calculus by the sensitization mechanism.

Several other cases are known in which calculus reformation occurred rapidly under hyaluronidase therapy, apparently due to sensitization. Presumably the phenomenon is not limited to calculi composed of cystine. Also, it has been possible to markedly facilitate the aggregation of crystals in the urines of persons who were

not predisposed to calculus formation by administering very small dosages of the enzyme, 15 units (1/10 ampul); presumably this represents sensitization. The frequency with which this reaction is manifested is unknown; probably it is not common. However, no person should receive repeated injections of hyaluronidase to prevent stone if the possibility of this reaction has not been ruled out. Butt² has described in detail how this preliminary test should be done. If turbid urine is rendered clear and free from sediment for a significant period of time by hyaluronidase, it is probable that the sensitization reaction is absent.

All patients in whom stones form do not have a turbid urine. Thus, clearance of turbidity cannot be used to rule out the sensitization reaction in patients with clear urine or to determine the proper dosage schedule. It should be obvious that if clear urine is rendered turbid by hyaluronidase that the sensitization reaction is probably present. Considerable experience is not available, but it is probable that a study of urinary films dried on glass slides as described by Butt should suffice to reveal the presence of the sensitization reaction in clear urine. Such slides may be studied with the ordinary medical microscope. If crystals tend to clump together on a properly prepared urinary film it is possible that the sensitization reaction is being manifested.

Fig. 3.—Cystine calculus resulting from sensitization reaction due to repeated subcutaneous injections of hyaluronidase. The insert in the upper right corner is cystine calculus removed from same kidney three months prior, before hyaluronidase therapy. The scale is in millimeters.

PROPER DOSAGE SCHEDULE

The determination of the proper dosage schedule in patients with clear urine requires special instruments. A study of urinary films under the Ultropak microscope is of value in such cases and may determine the proper dosage. It is emphasized that the Ultropak microscope is not to be regarded as a tool of utter precision for this purpose. Considerable experience is necessary in the use of this instrument in this almost unknown field in order

that the findings may be properly interpreted. Extreme variations occur in one and the same urinary film; much of this is probably artifactual and occurs in the making and drying of the slide. In the present state of knowledge the purchase of this expensive instrument for a study of this kind is not indicated.

Butt has found that the surface tension of urine is lowered by hyaluronidase, and he has used this phenomenon to set up a dosage schedule. It is possible to determine this effect clinically with a very simple instrument, although the result is only approximately accurate. I have found that hyaluronidase does lower the surface tension of urine, but not in all cases.

COMMENT

In general it appears that the results with hyaluronidase therapy have been unfavorable although some success has also been reported. It takes only a relatively short time for calculi to form but a much longer time to prove that any particular type of therapy has prevented them. The failures become apparent first. It appears that some of the failures may have been due to improper selection of cases; hyaluronidase therapy has been tried in types of cases in which our later studies have shown that it will not work. We have not treated a patient with the enzyme for long periods of time clinically. In our slight experience it has failed to prevent bladder calculi in recumbent patients.

In the present state of knowledge it would appear that hyaluronidase therapy is not indicated in most cases of calculi but may be tried in rapidly recurring cases in which the necessary dosage of the enzyme can be kept low (150-450 TRU daily). It may also be tried in cases in which our other regimens (after proper application) have failed and in which the factor of dosage necessary to keep turbid urine clear has been equilibrated with the cost of the enzyme on a long term basis and the desperateness of the particular case.

What has been said does not constitute an endorsement for the use of hyaluronidase therapy to prevent renal calculus. I wish to emphasize that I do not even know whether stone will be prevented if the turbid urine of a patient predisposed to calculus formation is kept clear and free of sediment by hyaluronidase therapy. From my studies it would appear that further work should be carried out on carefully selected patients, and such studies should be done critically with adequate laboratory controls on the basic science level.

SUMMARY AND CONCLUSIONS

The use of repeated subcutaneous injections of hyaluronidase to prevent renal calculus is not without danger. Occasionally stone formation may be facilitated by what is known as the sensitization reaction, said to be due to too small dosage of hyaluronidase. A case is presented in which there was rapid recurrence of a large cystine calculus in two months after surgical removal of a small cystine calculus from the same kidney. The patient received hyaluronidase subcutaneously for the two month period, and evidence is presented to justify the belief that the recurrence was due to hyaluronidase.

No patient should receive frequently repeated hyaluronidase injections to prevent renal calculus until certain

preliminary tests have been done to rule out the possibility of facilitation of stone formation. While the results of hyaluronidase therapy to prevent recurrence of renal stone have, in general, been disappointing, it would appear that further critical studies are indicated on carefully selected cases.

1101 Beacon St. (46).

BARIUM GRANULOMA OF THE RECTUM

REPORT OF A CASE

Harold L. Beddoe, M.D.

Saul Kay, M.D.

and

Sidney Kaye, M.S., Richmond, Va.

To the best of our knowledge, barium sulfate has not been described as the cause of a foreign body granuloma in the alimentary tract. The identification of barium as the cause of a polypoid submucosal lesion of the rectum furnishes the basis of this report.

Refvem,¹ by using polarized light, reexamined 209 lesions initially diagnosed as foreign body granuloma, granulation tissue, and chronic specific and nonspecific inflammation of the intestinal tract. He found foreign bodies in 53. Talc was the causative agent in 60% of these cases, with biotite, calcareous spar, and cotton comprising another 21%. Unidentified foreign bodies caused the other 19%. In his series, the highest incidence of foreign body granulomas was in the anorectal region, and 75% of these were due to talc. Barium was not identified in any of the cases.

Barium sulfate suspension has been observed entering the bronchi by accidental aspiration or through a tracheobronchial fistula.² Small amounts of barium in the lung are apparently not of serious consequence and may produce no symptoms. There are reports of barium entering the peritoneal cavity through perforations, traumatic or inflammatory, of the alimentary tract.³ We have observed two such cases; one in a patient with a perforated duodenal ulcer who was given a barium swallow under an erroneous diagnosis and one in a patient with an old ruptured appendix who also received a barium meal and showed barium emerging from the appendical opening. These cases will be published in more detail subsequently.

If death ensues from such a mishap, it is due to the resultant peritonitis and not to any peculiar property of

the barium itself. In one case, the barium was seen in roentgenograms of the abdomen four years after it entered the peritoneal cavity through a perforated duodenal ulcer at the time of fluoroscopy.^{3a} The patient remained asymptomatic.

Fig. 1.—A, photomicrograph showing intact rectal mucosa over rectal nodule ($\times 50$), and B, giant cells and scattered crystalline material in submucosa of foreign body-granuloma ($\times 100$).

There appears to be a general agreement that barium in small amounts may remain localized in the peritoneal cavity for an indefinite period without local complications or signs of toxicity. Histological proof of a granuloma produced by barium is presented in a paper by Masshoff.^{3c} There is also some recent experimental work on the effect of barium in the abdominal cavity,^{3b} and in the lungs.^{2b}

In the case reported by Masshoff a "pea-sized" nodule of smooth, rather firm, gray-white tissue was found on the posterior peritoneum near the level of the third lumbar vertebra in a 47-year-old woman who had undergone an operation for obstruction of the sigmoid colon caused by endometriosis. A colostomy was performed, and sometime prior to the second operation a barium enema had been given. There was no suspicion that barium had entered the peritoneal cavity, and it was only after examination of the nodule removed at the second operation for repair of the colostomy that the nature of the nodule was determined.

REPORT OF A CASE

A 53-year-old Negro man was admitted to St. Philip Hospital on June 19, 1953, with complaints of mild persistent pain in the midabdominal region for two months and of bright red blood in the stools for one month. Constipation had been intermittent for 8 to 12 months; there had been occasional vomiting. His appetite was poor, but he had no known weight loss. Roentgenograms of the gastrointestinal tract had been ordered

by his physician on May 7, 1953, before admission. Results of the barium enema were unsatisfactory, and a repeat study was made on May 28, 1953, using barium solution and tannic acid mixture with air contrast. The first films taken were unsatisfactory so a second enema was administered on the same day. No technical difficulties were noted during the administration of the enemas, and the patient did not complain of any pain during the procedures. No tumor or other abnormality was noted in the report of the roentgenogram.

Physical examination revealed a pedunculated tumor approximately 1 cm. in diameter palpable on the posterior wall of the rectum, 6 cm. above the anal orifice. No bleeding was observed. Internal hemorrhoids were present. The polypoid lesion was removed on June 22, 1953, and a hemorrhoidectomy was performed on June 25, 1953.

Pathological examination of the gross structure revealed a polypoid lesion measuring 1.2 by 1 by 0.3 cm. with intact rectal mucosa covering a rather firm gray-white circumscribed nodule. Microscopic study of the sections showed the rectal wall with an oval, circumscribed, granulomatous lesion covered by intact rectal mucosa (fig. 1A). The lesion was composed of fibroblasts, histiocytes, and multinucleated giant cells of the foreign body type arranged in haphazard fashion (fig. 1B). Scattered among the cellular elements were numerous doubly refractile crystals of various shapes, but appearing principally as rhomboid plates (fig. 2A). These were particularly evident with the aid of polarized light (fig. 2B).

In order to identify the foreign material responsible for the foreign body granuloma, a suspension of barium was examined under the microscope. Crystals were seen that were identical

Fig. 2.—A, photomicrograph showing greater detail of crystals and granulomatous reaction ($\times 200$), and B, the same with polarized light.

to those found in the tissue. To furnish conclusive proof, some of the tissue was sent to the toxicologist at the office of the State Chief Medical Examiner.

The following brief description is of the methods employed: A 5 gm. sample of fixed tissue (rectum) was analyzed for foreign metallic bodies. Spectrographic analysis was the procedure of choice for the detection of trace foreign metals. A Bausch and Lomb large quartz spectrograph was used (10 micron slit, 7.5 amp. direct current, and 60 seconds exposure

time, with arc illumination). The tissue was digested with nitric, sulfuric, and perchloric acids and then concentrated to 1 ml. The sediment and solution were transferred drop by drop into the crater of the positive carbon electrode and evaporated to dryness after each transfer. A few particles of finely ground carbon were added, and then the sample was arced. Characteristic barium lines were detected at 2,634, 2,596, 2,702, 2,785, 3,071, 3,262, and 3,501 Å. Control samples were then analyzed (normal colon) in an identical manner. Controls did not yield barium. Visual density comparisons were made with standard barium lines, and it was determined that the sample contained more than 1 mg. of barium in 5 gm. of tissue (20 mg. of barium per 100 cc.).

COMMENT

In this case, barium undoubtedly was deposited in the rectal wall during one of the barium enema examinations, although, theoretically, it would be possible for barium ingested orally to lodge in a crypt in the rectum and become sealed off later. The danger of perforation of the rectal wall by the tip of an enema tube has been emphasized.⁴ Traumatic injuries of the rectal mucosa following self-administered enemas are not infrequently seen by proctologists during routine sigmoidoscopic examinations.^{4c} The presence of a rectal polyp, hemorrhoids, or a fissure increase the possibility of trauma to the rectal wall. The enema tube may abrade the surface of a hemorrhoid or lodge momentarily at the base of the polyp or in a fissure and thus provide the site of entry for any solution subsequently administered during the examination. Such superficial injuries in the lower rectum may be entirely without pain to the patient and so pass unnoticed since the sensory nerve supply stops at the dentate margin. The patient in our case made no complaint of pain during any of the barium enemas.

The finding of a barium granuloma within the rectal wall in this patient leads us to believe that the mucous membrane was traumatized during a barium enema and allowed the escape of barium into the tissues. The barium suspension was then deposited within the submucosa with subsequent healing of the mucosal defect and development of a foreign body granuloma.

SUMMARY

A foreign body granuloma of the rectum caused by barium sulfate is reported. The cause of the lesion is discussed. This appears to be the first such case reported.

Physical Agents for Relief of Pain.—The use of water, usually in motion, is helpful in acute injuries to extremities. Contrast baths are especially helpful in treating osteoarthritis of the hands and feet. The use of the whirlpool bath seems to relax the muscles of the extremity which is immersed and to produce some relief of pain. . . . The application of cold packs or ice bags is often effective in relieving pain during the acute stages of sprains and strains and its analgesic effect seems to stem from two properties: (1) that of constriction of local blood vessels with resulting reduction in the amount of congestion and (2) the direct sedative effect upon the nerves themselves. This latter property is made use of in refrigeration anesthesia.—W. F. Wilhelm, M.D., and F. H. Krusen, M.D., *Pain from the Standpoint of Physical Medicine, Journal-Lancet*, October, 1953.

CONGENITAL RETROVERSION OF THE UTERUS DUE TO AN ABNORMALLY PLACED SIGMOID COLON

Joshua W. Davies, M.D., New York

This presentation does not deal with consistent distortions of the uterine fundus due to adhesions following an inflammatory process but with torsion and retroversion of the uterus due to a developmental anomaly of the sigmoid colon. Symptoms overlap the various fields of specialization and are of interest to the internist, orthopedist, abdominal surgeon, and gynecologist.

The sigmoid colon crosses the brim of the true pelvis at the sacroiliac articulation of the left side to end in the rectum. With the brim of the pelvis divided into twelve segments, the symphysis may be placed at six o'clock, the left infundibulopelvic ligament at three o'clock, and the sacroiliac articulation at two o'clock. A colon that is moder-

Fig. 1.—The uterus retrocessed and rotated counterclockwise owing to an adhesion between the sigmoid colon and the round ligament, Fallopian tube, and ovary on the left side. Contraction of the round ligament tends to draw the colon anteriorly rather than to act on the uterine fundus.

ately distended because of constipation does not encroach on the infundibulopelvic vascular pedicle, which carries blood vessels, nerves, and lymphatics to the left ovary and fallopian tube. Occasionally, however, the colon may be slightly displaced and enter the pelvis at three o'clock. By so doing it forces the infundibulopelvic ligament against the lateral pelvic wall and obstructs the venous flow of the left adnexa. Infrequently the colon may be displaced to the region of the left round ligament and be intimately attached to it. The left tube and ovary are thereby displaced and compressed by the overhanging colon, and the attachment of the round ligament to the sigmoid negates its function as a uterine stabilizer (fig. 1). Consequently there is retrocession and rotation of the uterine fundus, with resultant vascular stasis due not only to compression but also to angulation of the veins.

Because of the abnormal attachment of the gastrointestinal and reproductive organs there are symptoms referable to both systems. They may be vague and of varying degrees of severity, ranging from abdominal pain or discomfort,

accompanied by nausea, is present in the majority of patients. The nausea may be mild and listed among many indefinite symptoms, but occasionally it may be the dominant complaint. Spasm and reversed peristalsis lead to discomfort and fleeting pains in the flexures of the colon. At the ileocecal valve the spasm may be interpreted as due to chronic appendicitis. Rectal consciousness, resulting from sensations interpreted as due to pressure or burning, is conspicuous premenstrually and at the time of ovulation, when congestion is reflected to the adherent colon. Constipation, with or without hemorrhoids, is dominant.

Vascular symptoms are the result of stasis and lead to fatigue, edema, sacral discomfort, heaviness and numbness of the thighs, and paresthesia over various areas of the lower abdomen, thighs, and back. At times there may be a serous transudate from the rectum or the vagina. The vaginal secretion is not thick and tenacious, which

Fig. 2.—The colon after separation from the round ligament, tube, and ovary, with restored independent function of the previously adherent pelvic viscera. The opening in the peritoneum is closed with interrupted sutures that approximate the extremities of the dividing incision.

would suggest its origin in the cervical glands, nor is it thick and cheesy, which would suggest a vaginal infestation with Döderlein's bacillus (*Lactobacillus acidophilus*). The seepage is thin and watery and may be due to oversecretion by the congested endometrium, or to a transudate through the vaginal epithelium that follows the congestion of the pelvic lymphatics.

Fatigue is frequently due to venous congestion and the pooling of blood in the pelvic veins. Patients noticing fatigue usually feel much relieved after menstruation, provided the flow has not been too heavy. Occasionally a patient will confess that she seems to be losing her stamina and that she feels more rested and comfortable after sleeping on the abdomen. The assumption of the knee chest position affords temporary relief, and this observation has led many patients to the conclusion that something is at fault in the pelvis.

Heaviness and numbness of the thighs are the result of congestion in the veins that lie in and are supported by the visceral fascia adjacent to the peritoneum. This sup-

porting fascia envelops the sacral nerves and any displacement of the fascia by the engorged veins, lymphatics or edema may angulate or compress the sacral nerves. Numbness, paresthesia, and pain may follow compression or angulation of the sacral nerves. The nerve most frequently affected is the lateral femoral cutaneous nerve of the thigh, and its involvement explains the discomfort in the anterior aspect of the thigh below the inguinal ligament. The preperitoneal visceral fascia can be traced through the sacroiliac joint to the subcutaneous tissue of the back underlying the lateral depressions of Michaelis's rhomboid. Edema of this tissue may cause discomfort in the sacroiliac region, which is aggravated by faulty posture or sleeping on a soft mattress.

Gynecologic symptoms may be dysmenorrhea, menorrhagia, dyspareunia, sterility, early abortion, a sensation of tugging of the labia, and prolapse of the uterus. Dysmenorrhea is due to congestion and edema of the generative organisms, including the peritoneum of the pelvic viscera, and imperfect drainage from the uterus. Menorrhagia is probably due to venous congestion that follows a kinking or stasis of the uterine or ovarian veins. The process may extend to the formation of pelvic varices. Frequently the menstrual periods may last as long as seven days, and while the blood loss may not be debilitating, there is a consciousness of the flow that in itself imposes certain restrictions, both physical and psychic, on the woman. Reduction of the menstrual flow from seven to five days will, in the course of a year, represent almost an extra month of freedom from bleeding.

Dyspareunia is to be expected with engorgement of the pelvic peritoneum. If gentle pelvic manipulation is painful, added congestion due to emotion and the fear of pain from pressure on a fixed uterus may strain a harmonious marital relationship. The cure is surgical and not psychiatric therapy. Sterility or early abortion may be one of the first complaints, because the maternal instinct usually overshadows physical discomfort. The sterility, perhaps, is due to venous congestion and angulation of the tubes brought about by the displacement and twisting of the uterus. Tubal spasm may follow irritation by the overhanging sigmoid colon. Should pregnancy be established, there is the possibility of abortion due to cervical dilatation that accompanies the inability of the uterus to expand into the abdominal cavity.

The sensation of tugging of the labia is due to the involuntary spasm of the muscle in the round ligaments of the uterus that traverse the inguinal canal to insert in the labia majora. The tugging is an attempt to pull the retroverted uterus to normal position and is most apparent immediately after voiding. Prolapse of the uterus in young women may follow retrodisplacement of the uterus. Such a displacement should not be treated entirely from below, but should include an exploration from above to determine whether the uterus is drawn posteriorly by the sigmoid colon. If so, steps should be undertaken to correct such congenital displacement.

Diagnosis is difficult because of the overlapping of complaints. A pelvic examination by a gynecologist aware of dysfunction due to a displaced sigmoid is important. He may be able to discern a retrocessed uterus

that is drawn to the left and slightly rotated. Increased resistance to the examining finger by the paracervical supports of the left side suggests a left-sided disturbance that should be discussed with the referring physician, who may be able to institute corrective bowel therapy. Especially is this advisable in patients who have been operated on for chronic appendicitis and then complain of pain in the lower left quadrant of the abdomen, spasm of the rectum, and apprehension.

Treatment is at first medical. An accurate diagnosis even with the aid of roentgenograms of the colon is uncertain, but the gynecologist should be aware of congenital displacements of the colon that may alter normal gynecologic function. Whenever the abdomen is opened for the relief of a symptomatic fixed retroversion of the uterus, it is not enough to perform a round ligament fixation operation without determining whether an abnormally placed sigmoid may be a factor in causing the retroversion. A slightly displaced sigmoid colon may be readily restored by incising the fine bands that may draw the sigmoid upon the infundibulopelvic ligament, but an attachment between the sigmoid and the round ligament is treated by incising the peritoneum, which unites them, parallel with the colon and then closing the opening in the opposite direction so that the sigmoid will be displaced toward the sacroiliac area (fig. 2). Even though one may detect a violent contraction in the round ligament after its division from the colon, it is advisable to perform a round ligament shortening operation that will draw the appendages anterior to the colon. Occasionally the cecum or terminal ileum may be adherent to the right round ligament and the division of congenital attachments between them is advisable if one wishes to maintain the independence of the various systems.

SUMMARY

The sigmoid colon enters the pelvis at the sacroiliac joint. In this segment it does not drag upon the infundibulopelvic ligament, which carries blood, lymph, and nerves to the left adnexa. Occasionally the colon overhangs the vascular infundibulopelvic ligament. Further displacement may compress the left tube and ovary. An attachment between the sigmoid and the left round ligament may cause torsion retroversion of the uterine fundus, with symptoms referable both to the reproductive and gastrointestinal systems. The independent function of the two systems may be established by incising the peritoneum parallel with the colon and closing the diamond-shaped raw area so that the separated structures will be as far removed as possible.

580 Park Ave (21).

Hypotension.—Hypotension is a manifestation of a disturbance in the mechanisms sustaining the level of the blood pressure in the cardiovascular system. The maintenance of a normal level of blood pressure is dependent on several simultaneously interacting circulatory adjustments that include sufficient cardiac output to meet the metabolic demands of the tissues, adequate arteriolar constriction to maintain the peripheral resistance, and the presence of an effective circulating blood volume. Disturbances in any one or combination of these homeostatic mechanisms, or an imbalance in them, cause a fall in the arterial pressure.—W. E. Judson, M.D., *Hypotension: Physiologic Mechanisms and Treatment, Medical Clinics of North America*, September, 1953.

RESECTION OF AORTIC BIFURCATION AND REPLACEMENT WITH HOMOLOGOUS GRAFT FOR ANEURYSM

D. Emerick Szilagyi, M.D.

and

John A. Hemmer, M.D., Detroit

Treatment by resection of the aortic bifurcation and grafting is a very recent addition to the methods of management of abdominal aortic aneurysms. A bibliographic survey through April, 1953, disclosed only one recorded successful instance of such an operation, namely the case of Dubost and associates.¹ Schafer and Hardin² reported a similar case that, however, ended fatally owing to disruption of the aortic anastomosis on the 29th postoperative day. We know, however, of three other instances in which the procedure was performed successfully.³ Because of the scarcity of recorded experience with this form of therapy, an account of the following case may have interest.

REPORT OF A CASE

The patient was a 69-year-old white man who was first seen at the Henry Ford Hospital on Nov. 26, 1952, for the complaint of constipation. Subsequent investigation revealed nothing of further importance about this complaint, but the systemic survey showed that the patient had had severe intermittent claudication of his left leg for five years, and physical examination demonstrated the presence of a large pulsating mass in the upper left side of the abdomen. Questioning disclosed that the patient had first been told about a pulsating abdominal swelling two years earlier and that he had received intravenous injection treatment for peripheral vascular insufficiency, with some relief. At the time of his present admission he could not walk 200 yd. (60.96 m.) without serious discomfort.

On examination the patient seemed slightly younger than his age. He appeared healthy and his state of nutrition normal. He showed evidences of mild to moderate generalized arteriosclerotic changes. In the midabdomen, slightly to the left of the midline, there was a mass measuring about 6 by 6 by 8 cm.; it was slightly tender, movable, expansile, and pulsating. The outward appearance of the extremities was normal. There were easily palpable femoral pulsations. The left dorsalis pedis and posterior tibial arterial pulsations were not palpable. The pulsation of the right posterior tibial artery was moderately strong, while the presence of the right dorsalis pedis pulsation was questionable. The remainder of the physical examination showed nothing worthy of note. The results of the blood serological, morphological, and chemical studies were normal. Liver and renal function tests, chest radiograms, and electrocardiograms likewise showed no important abnormalities.

A translumbar aortogram⁴ confirmed the clinical impression of the presence of an aortic aneurysm (fig. 1). The lower border of the aneurysm was located 2.5 cm. proximal to the aortic bifurcation, while its upper limit reached a point 3 cm. distal

to the level of the right renal artery. Retrograde iliac arteriograms showed a patent vascular tree with advanced atheromatous intimal changes. Although the latter finding raised some misgivings about the suitability of the iliac vessels for anastomosis, it was decided to attempt a resection and replacement of the aortic segment bearing the aneurysm.

On Dec. 20, 1952, the patient was anesthetized with intraspinal administration of procaine (Novocaine) hydrochloride, and a cross-shaped midline and transverse incision was made. The aorta and its main divisions were exposed through the posterior parietal peritoneum from the lower border of the pancreas downward to a level midway between the bifurcations of the common iliac arteries and the ligaments of Poupart. The disposition of the aneurysm was very much the same as suggested by the aortogram, but its size was about half again as large (fig. 2). By peeling the left kidney out of its capsule and dislocating it upward and medially, thereby displacing the left renal vein in the same direction, a 2.5 cm. segment of the aorta could be freed between the upper limit of the aneurysm and the lower border of the right renal artery. After placing loose slings of tape around the aorta above and around the common iliac arteries below, the main body of the aneurysm

pleting the anastomosis. The anastomosis of the left common iliac artery to the graft left so much to be desired that a small polyethylene catheter was placed in situ directly proximal to the anastomosis for postoperative regional heparinization. All suture lines were covered with fascial strips taken from the

Fig. 1.—A, preoperative translumbar aortogram showing aortic aneurysm; B, the same six weeks after surgery showing patent aortic and iliac anastomoses.

was dissected from its posterior connections with ease after dividing the second and third paired lumbar arteries. The inferior mesenteric artery coming off the midpoint of the aneurysm was also tied and cut. The aorta was occluded by crowding a Potts ductus clamp against the lower border of the right renal artery; the common iliac arteries were secured in bulldog clamps directly proximal to the hypogastric branches; and the aneurysm was resected.

A 13-day-old graft that was preserved in modified Tyrode's solution⁵ was used to reestablish vascular continuity. The anastomosis between the upper end of the graft and the extremely sclerotic aortic stump presented some difficulties but was accomplished without too much delay. However, the union of the iliac limbs of the graft with the iliac arterial stumps presented a serious problem because of the atheromatous decay of these arteries. It was necessary to excise long segments of atherosclerotic intima from these vessels before com-

Fig. 2.—Drawing showing appearance of aneurysm at operation.

Fig. 3.—Drawing showing graft in place.

pleting the anastomosis. The anastomosis of the left common iliac artery to the graft left so much to be desired that a small polyethylene catheter was placed in situ directly proximal to the anastomosis for postoperative regional heparinization. All suture lines were covered with fascial strips taken from the posterior rectus sheath (fig. 3). It may be noted that the abdominal aorta was clamped for one hour and 20 minutes. The total operating time was five hours and 30 minutes. Microscopic examination of the aneurysm showed it to be atherosclerotic in origin.

5. Gross, R. E., Ell, A. H., Jr., and Pierce, E. C.: Methods for Preservation and Transplantation of Arterial Grafts: Observations on Arterial Grafts in Dogs: Report of Transplantation of Preserved Arterial Grafts in Nine Human Cases, *Surg., Gynec. & Obst.*, 88: 689-701 (June) 1949.

After operation, the right lower extremity regained its usual vascularity in from 30 to 60 minutes. On the left, however, the state of the limb at first looked alarming. From just below the knee downward, the leg was cold, mottled, bluish-grey, and almost entirely devoid of sensory and motor response. Heparin was administered as a continuous drip through the left iliac intra-arterial catheter. Two hundred to 300 mg. of heparin was given in 1,000 to 1,500 ml. of 5% dextrose daily for 10 days. The clotting time, as determined four times daily on venous blood obtained from the left foot, was kept between 12 and 14 minutes. The limb gradually improved, and 72 hours postoperatively it had regained its preoperative appearance. The femoral pulse, however, remained the only palpable pulsation in the limb.

In other respects the postoperative course was at first hectic. Almost complete anuria, wound disruption, and phlebothrombosis had to be dealt with in turn. Phlebothrombosis necessitated the resumption and continuation of anticoagulant therapy (first with heparin intravenously and then with bishydroxycoumarin [Dicoumarin] orally) until the 28th postoperative day. By the 15th postoperative day, the patient's condition had improved sufficiently to permit ambulation with a normal gait. There was no impairment of the sensory or motor nerve distribution of the lumbar or sacral spinal cord. Hospitalization was prolonged by the slow healing of the operative incision that eventually developed into a large hernia that will require later repair. When the patient was discharged on the 42nd postoperative day, his only complaint was mild intermittent claudication of the left lower limb on moderate to severe exertion. At this time all but one of the pulsations of the lower limbs were readily palpable; the left posterior tibial arterial pulse could not be palpated. During the following seven and a half months, the patient's good general condition persisted, and intermittent claudication gradually disappeared. A translumbar aortogram six weeks after operation showed patent aortic and right iliac anastomosis of normal width; the left iliac anastomosis was also patent but slightly narrowed (fig. 1B).

SUMMARY

A report is given of a case of atherosclerotic abdominal aortic aneurysm that was treated with resection of the aortic bifurcation and replacement by homologous graft. During a period of observation of eight months, the result of the operation remained excellent.

The Physician and His Patient.—In . . . medical practice, the physician's personality is one of . . . the most potent therapeutic tool[s] he can use. . . . Patients come to doctors with so many different attitudes. Often they are fearful. Some come expecting magic. Some times they come only to please someone else. Some times they come in to be defiant. They may come because they want corroboration, or to obtain sympathy and attention, or to be told what to do. Some even come with the intent to deceive the physician. On the other hand, the physician himself is a person with his private prejudices, defenses, blind-spots, ignorance. These can be reflected in excessive tests and examinations. . . . Some times his uncertainty is expressed in his use of platitudes or placebos, or a know-it-all attitude. Not infrequently, I am sure, some of us become irritated or annoyed, conceivably even vindictive and hostile. . . . This interpersonal relationship is one of the salient points of all psychotherapy. Whether he knows it or not, every physician uses psychotherapy. It may be good or bad, depending upon his attitudes, actions and reactions, his conduct, his ability to listen, his knowledge in knowing what to say and when to say it. If and when our psychiatric knowledge of this all-important phase of our professional work can be imparted more adequately and more clearly to medical students, we can expect a further improvement in the practice of medicine.—W. C. Menninger, M.D., Psychiatry and the Practice of Medicine, *Bulletin of the Menninger Clinic*, September, 1953.

TRANSPALATINE SURGERY FOR CONGENITAL BILATERAL CHOANAL ATRESIA

REPORT OF A CASE

James S. Walker, M.D., Urbana, Ill.

Congenital bilateral choanal atresia was reported first as an observation at autopsy by Otto¹ in 1829. Medovy and Beckman² have collected 115 cases from the literature up to 1945. Subsequently Owens,³ Cohen and Witchell,⁴ Hanckel,⁵ Aboulker,⁶ Whitehouse and Holt,⁷ and Johnson⁸ have added eight cases. Flake⁹ has treated a series of 25 patients not reported on. The anomaly probably results from an abnormal embryologic development. In the formation of the nasal passages, the nasobuccal membrane invaginates into the forming nose and migrates posteriorly as a blind pouch. Similarly, the buccopharyngeal membrane moves into the choanal area from the posterior aspect. Normally, the two rupture at their points of contact and the nasal passages are formed. Persistence of either membrane or the mesodermal elements between them gives rise to an occlusion of the choanae that may involve one or both sides. Ninety per cent of these obstructions are bony.

The birth of an infant without a nasal airway is a true medical emergency. The salient features are recurrent cyanosis, mouth breathing, dysphagia, and nasal discharge. Feeding attempts cause respiratory embarrassment and may result in the aspiration of foreign material into the tracheobronchial tree. Malnutrition will develop quickly. The diagnosis can be established easily and promptly. The failure of a small catheter to pass through either nostril into the pharynx is indication for further investigation. Roentgenograms of iodized oil instilled into the nasal cavities provide pictorial confirmation (fig. 1 and 2).

Except for Cinelli's¹⁰ report that advocated two full years of nursing care before surgical intervention, most opinion favors early surgical relief. In many infants, a tracheotomy has been performed in an effort to improve nursing ability prior to nasal surgery. Surgical correction is attempted by an intranasal, transantral,¹¹ or a trans-

From the Department of Otolaryngology, Carle Memorial Hospital, and Carle Hospital Clinic.

Dr. James Hooker made the diagnosis and handled the medical aspects of this case.

palatine approach. The intranasal route has been used successfully in the newborn in this country. This procedure involves the use of drills, trocars, curets, chisels, forceps, caustics, and electrocautery. The last two methods are particularly useful in the membranous type of obstruction. The transantral approach has not been used in infants.

Fig. 1.—Anteroposterior roentgenogram showing retention of radiopaque oil instilled into the left nasal passage. A study of the right nasal passage was identical.

In contrast to the blind intranasal approach, the transpalatine route offers surgery under direct vision. In this technique, the reflection of a palatal flap and resection of the hard palate are used for exposure of the atretic site. The details of this technique are well illustrated and described in articles by Ruddy,¹² Owens,³ Hanckel,⁵ and Dolowitz.¹³ Despite the increased interest in transpalatine surgery, there remains a dearth of reports relative to infants below six months of age. Only five have been recorded, four of these by Aboulker in the foreign literature and one by Hanckel in the United States. This case report serves to illustrate that corrective surgery of congenital bilateral choanal atresia under direct vision is feasible in the very young infant. No special equipment is required, and the transpalatine operation is technically within the capabilities of the average otolaryngologist.

REPORT OF A CASE

A white female infant was born at term, Feb. 10, 1952. Delivery was spontaneous and without difficulty. The birth weight was 7 lb. 7 oz. (3,373 gm.). She was admitted to the Carle Memorial Hospital on April 6, 1952, with complaints of (1) difficult, noisy breathing, (2) recurrent cyanosis, (3) poor ability to nurse, (4) profuse nasal discharge, and (5) loss of weight. The infant then weighed 6 lb. 6 oz. (2,891 gm.), appeared malnourished, and breathed laboriously. Her nose was filled with a thin purulent discharge. Except for the nasal symptoms, the physical examination revealed no abnormalities. Suspecting choanal atresia, the examining pediatrician attempted to pass a small nasal catheter through each nostril

without success. The tentative diagnosis of congenital bilateral choanal atresia was later confirmed by roentgenograms of iodized oil in the nasal cavities. By constant attendance and careful nursing care, the infant gradually reached the weight of 7 lb. (3,175 gm.) at 10 weeks of age. At this time (April 21) the choanal atresia was resected by the transpalatal approach. A Crowe-Davis mouth gag was employed to expose the area, and the operator sat at the head of the patient. No difficulty was experienced with the ether anesthesia. The surgical technique outlined by Ruddy was followed. This consisted of a semicircular incision parallel to the alveolar ridge. A posteriorly hinged membranous flap was turned back, exposing the hard palate. Resection of the hard palate uncovered the atretic area, and a subperiosteal dissection of the mucous membrane was done. The obstruction was composed of hard bone. It was removed along with the posterior part of the septum by the use of chisels, curets, and biting forceps. The blind membranous pouches were easily identified and opened, and the lining membrane covered most of the raw areas. A single perforated no. 8 F. catheter was used as an obturator and was inserted into the left nostril and passed posteriorly into the nasopharynx. Under direct vision this tube was then doubled and passed anteriorly through the right nasal passage. The two free ends were sewed together, eliminating anchorage to tissue. The loop formed in the posterior portion of the nose thus served as a gentle dilator exerting mild lateral pressure and was moved back and forth daily to break adhesions. A change of obturator material was easily accomplished by sewing a new catheter to the old. Withdrawal of the old catheter brought the new into position. This simplified the problem of cleanliness and avoided damage to the soft tissues.

The postoperative course was uneventful. The patient gained 6 oz. (170 gm.) in the first week. A tiny fistula developed anteriorly but closed on the third postoperative day. The sutures and the catheter were removed on the 14th day. Bouginage was carried out with catheters for one week but, because of apparent developing stenosis, two short lengths of no. 10 F. catheters were inserted and anchored to the septum on May 12. The patient was released from the hospital on

Fig. 2.—Roentgenogram taken from side, showing retention of radiopaque oil in the left nasal passage. The outline at the top is the thumb of the attendant holding the patient's head.

this date, weighing 7 lb. 7 oz. The tubes were removed seven days subsequently, and the airway was excellent. Bouginage was carried out weekly until September. On Sept. 19 the child was anesthetized and the nasal airway dilated up to the size of a no. 16 F. esophageal bougie. Bouginage was again employed weekly until November, 1952. Although the child was able to tolerate the passage of a no. 14 F. bougie in the office, an examination of the nasal passages was carried out

12. Ruddy, L. W.: A Transpalatine Operation for Congenital Atresia of the Choanae in the Small Child or the Infant, *Arch. Otolaryng.* **41**: 432 (June) 1945.

13. Dolowitz, D. A., and Holley, E. B.: Congenital Choanal Atresia, *Arch. Otolaryng.* **49**: 57 (June) 1949.

with the patient under general anesthesia on Nov. 21. A definite rim of bone could be palpated with mastoid curets in each nostril. These areas were simply smoothed down, and a rubber tubing with an outside diameter of 6 mm. was anchored in the same fashion as the original catheter. The tubing was removed Dec. 12. Further therapy has not been necessary, and an excellent nasal airway has persisted. The patient has gained weight constantly, and on the last examination, May 12, 1953, she weighed 20 lb. 5 oz. (9,212 gm.). On Jan. 25, 1954, the patient was reported to weigh 30 lb. (13.6 kg.) and to be asymptomatic.

CONCLUSIONS

The diagnosis of congenital bilateral choanal atresia is made easily and may be suspected in an infant with recurrent cyanosis, feeding difficulty, mouth breathing, and nasal discharge. It is probable that some infants who have died with the diagnosis of asphyxia neonatorum were in reality victims of complete nasal atresia. A few patients have been known to survive. Surgical relief of the obstruction is imperative. Postponement of surgery until the patient can tolerate the conditions is risky and undesirable. The transpalatal approach is feasible in the young infant, offers surgery under direct vision, and does not require special instruments. Hanckel concluded that closure of the palatal wound was unnecessary because the palatal flap was always sloughed in patients under 6 months of age. Inasmuch as healing by primary intention was obtained in this patient, it seemed advantageous to close the incision. The astute physician caring for the newborn will uncover more cases in the future. The surgeon has an excellent opportunity to improve the survival rate. No previous experience is necessary to handle a case properly.

Lead Poisoning in the Pewter Era.—Just what pewter is defies simple definition. To the metallurgist, pewter is any one of a series of alloys in which tin is the dominant metal hardened by small additions of antimony, copper and bismuth. By popular consent, pewter is an alloy of tin and lead, the latter at a level of about 10%. Among the (American) colonists, pewter was any metal that might be shaped into useful objects with the meager facilities available. At times all was lead, and a 50% lead content was common. . . . The early settler was not the sort, nor was there opportunity, to have arrived accompanied by neat crates and barrels of deftly packed china and silverware. . . . Pewter lent itself to spoons, mugs, plates, porringers, tankards, tobacco jars, lamps, candlesticks, and storage vessels for foods and alcoholics. . . . The tinsmiths of England during and before the colonial period were aware of the undesirable properties of any lead content in pewter. They sought to regulate the percentage in pewter, at times demanding its elimination as a constituent. Always one argument was the harmful properties of lead. The quality of pewter descended with the increased content of lead. As a rule this poor quality (trifle, sad ware, lay metal) was shipped off to America or was fashioned there. Firm was the belief that a percent of lead at or below 10% was harmless. The demand for lower percentages was admirable, but if the truth had been known, 10% was sufficient to have induced lead poisoning under many circumstances. . . . The 1723 enactment of the Massachusetts Bay Colony prohibiting the distillation of rum through pewter stills and still heads is remarkable and perplexing. It is remarkable that without any exciting precedent this protective legal measure quickly followed the complaint from North Carolina rum drinkers of ill effects produced by New England rum. It is perplexing that no information reveals the medical guidance leading to the enactment.—C. P. McCord, M.D., *Lead and Lead Poisoning in Early America: The Pewter Era, Industrial Medicine and Surgery*, December, 1953.

SPECIAL ARTICLE

THE MEDICAL AND HOSPITAL PROGRAM OF THE VETERANS ADMINISTRATION

AN EXAMINATION OF CERTAIN POPULAR MISCONCEPTIONS

*Adm. Joel T. Boone (MC), U.S.N. (Ret.),
Washington, D. C.*

I have always felt that when a magazine publishes an article its readers have the right to expect at least two things: first, that the author knows what he is talking about and, second, that his material is reasonably informative and interesting.

My position and experience as Chief Medical Director of the Veterans Administration and the head of its Department of Medicine and Surgery may offer some assurance that I meet the requirements of the first point; as to the second, it seems to me that what is factual and of direct concern not only to physicians but to every American taxpayer ought to invite, at the very least, sufficient interest to encourage informative reading.

Misconceptions about the Veterans Administration's medical and hospital program are numerous. They are to be found in almost any group. They may be seen in the pages of some of even the most carefully edited newspapers; in popular magazines, usually those with a penchant for breathless advance notice about the very latest in "miracle drugs"; and even in medical journals.

Such widespread misconceptions or even just plain ignorance by distorting medical facts—as I expect to show—into half-truths, or downright untruths, can do great damage to the medical and professional standing and accomplishments. Lack of information also does a great deal of mischief to public understanding of what Veterans Administration medicine is accomplishing, how it is being accomplished, and why it is being done as it is.

To put the matter bluntly, wrong is wrong and should be set right. In common fairness to veterans, the government, to every loyal, hard working member of the Veterans Administration's Department of Medicine and Surgery, to the American medical and ancillary professions—to say nothing of our taxpaying fellow citizens throughout the United States—the Veterans Administration's medical and hospital program deserves to be discussed in terms of factual accuracy.

Now, good faith is an admirable quality, but the fact that many misconceptions about the Veterans Administration may be passed from one uninformed person to another in entire good faith does not lessen by a feather-weight the grievous injury done to veterans and their loved ones, to the Veterans Administration's Department of Medicine and Surgery, or to the American medical profession, whose cooperative work is so often misunderstood, whose high motives are so hastily maligned, whose all-important professional integrity is sometimes mis-

Chief Medical Director, Veterans Administration.

takenly assailed by persons who are uninformed, albeit of good intent. Some, of course, fully informed may have less admirable motives.

I now respectfully invite my readers to examine, with me, the "A to Z" record of certain prevalent misconceptions about the Veterans Administration's medical and hospital program. If some patent examples are omitted, it is only because the list is too long for a treatise of this scope. Here, then, are some prime examples of medical misinformation about the Veterans Administration, followed in each case by a brief statement of the fact:

- (A) "*I hear that . . . 90% of patients in VA hospitals (in some statements the percentage used was 80% or two-thirds) are being treated for non-service-connected disabilities.*"

Considerable interest has been centered on the authority of the Veterans Administration to hospitalize veterans for conditions not attributable to military or naval service. Even when this authority is not questioned, questions have arisen concerning the degree to which Veterans Administration's beds are used for the care of veterans requiring hospitalization for service-connected conditions as compared to the number of beds provided for veterans requiring care for non-service-connected disabilities. To understand more clearly the composition of the patient load of the Veterans Administration, it is important to consider not only their legal status but their clinical condition as it relates to chronic illness. The most recent statements on the clinical and legal status of veterans hospitalized under Veterans Administration auspices are those pertaining to the approximately 105,000 patients in hospitals on Jan. 31, 1953. Of these: 0.8% were non-veterans (U. S. armed forces personnel, humanitarian cases, etc.); 37.4% were veterans receiving care for service-connected disabilities; 9.8% were veterans discharged from a military service for disabilities incurred in line of duty or veterans in receipt of compensation for service-connected disabilities who were receiving care for other disabilities; and 52% were other war veterans treated for non-service-connected disabilities.

To stop at this point in discussion of the legal eligibility of the Veterans Administration's patient load is to ignore the underlying concept implied in the legislative acts providing bed facilities beyond those necessary for the care of veterans suffering from service-incurred disabilities. Let us therefore examine the nature of the disabilities currently being treated in that portion of the total Veterans Administration bed facilities allocated to the care of veterans with non-service-connected disabilities only, that is, the group representing 52% of the total patients.

This group can be initially subdivided as follows: 32.3%—patients with conditions that are known to be chronic in nature, and 19.7%—patients with presumed nonchronic conditions. In the first group I have included veterans hospitalized for the treatment of tuberculosis or psychosis as well as those hospitalized for some other chronic disability as evidenced by the fact that, on the particular census day, they had already been hospitalized for more than 90 days. These undisputedly chronically ill patients total 33,866, or 32.3% of all patients. The rest of the patient load, veterans with presumably "nonchronic" disabilities, constitute 19.7% of the total patients. When

we examine the composition of the so-called nonchronic cases we find evidence to suggest that many of them are in truth chronically ill; for example, of the 20,642 veterans with presumed "nonchronic" disabilities, 6,516 patients, or 6.2% of all patients, are in receipt of or have applied for a VA pension for a permanently and totally disabling non-service-connected condition. These veterans, in addition to their severely incapacitating disability, must have incomes less than \$1,400 a year if without dependents or \$2,700 with dependents to be eligible for VA pension. While these veterans had been hospitalized for less than 90 days when the census was taken, it appears likely that because of their severe disabilities they will require long-term hospitalization. More than half of these veterans were being treated for one of the following chronic conditions: cardiovascular disease, cancer, neurological disease, or arthritis.

Another small subcategory of interest that had been included in the "nonchronic," non-service-connected class are 3,662 patients (or 3.5% of the total patient load) who on the day of the census had a claim for compensation for a service-incurred disability pending adjudication action. A significant percentage of these claims for compensation are subsequently adjudged to be service-incurred or service-aggravated disabilities and therefore would permit the reclassification of these veterans to the service-connected category.

The residual group of veterans with "nonchronic," non-service-connected conditions in hospitals comprise 10,464 patients (or 10% of the total patient load). How many of these patients may require long-term hospitalization is a moot point. One-third of these patients are found to be suffering from one of the following serious disabilities: cardiovascular disease, cancer, or neurological disease, or arthritis.

In summary, an examination of the composition of the current VA patient population makes it evident that the question of the legal eligibility of veterans is somewhat complex. It becomes obvious that a description of the patient load in terms of two classes, patients with service-connected disability and those with conditions that are not service connected, is an oversimplification. On legal grounds, there are three and not two categories of veteran patients: (1) veterans treated for service-connected disabilities, (2) veterans with compensable service-connected disabilities treated for non-service-connected disabilities only, and (3) other eligible veterans treated for non-service-connected disabilities. Moreover, on clinical grounds, we find a relatively small percentage of VA beds are used for the treatment of patients with "non-chronic" disabilities that are not service connected.

- (B) "*I hear that . . . veterans with non-service-connected ailments sign a pauper's oath to get into a Veterans Administration hospital, and the Veterans Administration makes no effort to check for fraudulent oaths.*"

The law does not require a pauper's oath. The law does permit the applicant to make a statement under oath to the effect that he cannot afford to pay for necessary treatment elsewhere. There is a considerable difference, as but a cursory thought will reveal. Further, the law specifies that the statement under oath shall be accepted by the

Veterans Administration as sufficient evidence of the applicant's inability to defray necessary expenses. There is contained on the form for application for hospital treatment or domiciliary care a statement of the penalty prescribed by statute for making false statements or claims, and the applicant, or if he is incompetent, his representative, is required to sign that he understands its import. In addition, the applicant must provide information concerning his financial status, including income, any savings or property holdings, and expenditures. If anyone will charge in writing that a Veterans Administration patient has committed fraud in the matter, the Veterans Administration will refer the case at once to the Department of Justice for any action deemed appropriate. The Veterans Administration is without authority to require verification of a war veteran's statement and is not responsible for criminal investigation or prosecution.

(C) *"I hear that . . . patients with non-service-connected disability are encouraged by the Veterans Administration to be dishonest in preparing applications for hospitalization by claiming pauperism."*

Criminal fraud of this kind is punishable, upon conviction, by fine or jail term or both, under Public Law 2, 73rd Congress, or other statute. I know of no such practice. Those who claim they do should, and have a duty to, present any evidence they have to the proper authorities. Every American citizen has an obligation to present valid information of perpetrated fraud so that the culprit may be prosecuted.

(D) *"I hear that . . . too many hospitals have been built by the Veterans Administration. Right now there are more than are needed to serve eligible veterans."*

This contention is completely refuted by the size of the waiting list of veterans seeking admission to Veterans Administration hospitals. The waiting list of veterans who are eligible for hospitalization and who have been certified by the Veterans Administration as needing hospitalization has averaged more than 17,000 every day in the week for many months. Further, the Veterans Administration has built no hospitals except as directed by authorizing statute and appropriation acts.

(E) *"I hear that . . . thousands of Veterans Administration hospital beds are standing empty because there are not enough patients to keep them filled."*

Veterans Administration hospital beds are not empty because of a lack of patients. The waiting lists of veterans seeking admission refute any such contention. Empty beds exist in Veterans Administration hospitals because of personnel recruitment difficulties or because of construction projects that are under way.

(F) *"I hear that . . . patients are kept in Veterans Administration hospitals far longer than necessary, longer than the normal stay in a non-Veterans Administration hospital."*

When attempts are made to compare the lengths of stay of patients in Veterans Administration hospitals with those in non-Veterans Administration hospitals, quite erroneous conclusions are likely to result. It is difficult, if not entirely illogical, to attempt to compare two dissimilar groups. I do not need to point out what constitutes the patient load of a non-Veterans Administration hos-

pital. The patient load of Veterans Administration hospitals is constituted, for the most part, of an aging population characterized by a greater frequency of multiple disabilities and chronic disorders that are less amenable to treatment and that require longer care. Approximately half of the patients in Veterans Administration hospitals are veterans of World War I or earlier periods of service with a median age of 61 years. The median age of World War II patients is 36 years. Other hospital systems do not present comparable situations, and therefore comparisons are of little significance. The chronic nature of the Veterans Administration patient load is indicated by the fact that over 51% of the Veterans Administration patients in hospitals on Jan. 31, 1953, had already spent more than a year on hospital rolls as Veterans Administration patients. This situation will become even more accentuated with the passing of time. There are other factors that influence the lengths of stay of patients in Veterans Administration hospitals that are not generally known. The accessibility of the patient and the hospital to each other, the nature of the service provided in the Veterans Administration hospital, and special requirements for medical evaluations having a bearing on the veterans' legal status all are of significance.

When a patient is hospitalized by the Veterans Administration, it is necessary not only to treat the disability that caused the patient's hospitalization but also to study, evaluate, and treat other concomitant disabilities the patient may have, since pension and compensation payments may be affected. When it is realized that compensation and pension payments for the fiscal year 1953 amounted to \$1,768,225,496, the importance of this phase of a veteran's hospitalization cannot be minimized. Further, it is common practice for a patient who enters a non-Veterans Administration hospital to have already had preliminary examinations and laboratory tests, and it is not usual to retain such a patient in the hospital until medical attention is no longer called for. The patient's treatment in this class is continued and completed after his release from the hospital by his doctor. All this cuts down the length of stay of the patient in the non-Veterans Administration hospital. The situation that prevails in patients cared for by Veterans Administration hospitals is not analogous. The hospital must start its medical work-up on its patients from the beginning and must carry it to completion, since only patients with service-connected conditions may be cared for on an outpatient basis.

Finally, the lengths of stay of Veterans Administration patients are influenced by the necessity, in many instances, for properly arranging for the patients' post-hospitalization care. The more aged patients may be afflicted with considerable residual disabilities upon conclusion of treatment. A moment's thought will demonstrate the necessity for retaining them in the hospitals until suitable arrangements can be effected for their post-hospitalization care.

(G) *"I hear that . . . Veterans Administration hospital construction is a waste of public money. They cost more to build per bed than do non-Veterans Administration hospitals."*

The "cost-per-bed" argument is illogical and completely misleading; however, even when this is used as a computation, the cost of Veterans Administration hos-

pitals has been found to compare favorably with non-Veterans Administration hospitals throughout the country. A far more reasonable comparison is cost-per-square foot of floor space or cost-per-cubic-foot of content. Because of the types of patients and the requirement that complete medical service must be rendered, Veterans Administration hospitals of necessity contain space and equipment for various kinds of therapy, space and equipment for rehabilitative measures, dining facilities, administrative offices, chapels, libraries, none of which provide beds, all of them requiring space. Considerations like these make "cost-per-bed" statistics completely misleading.

(H) *"I hear that . . . some patients who enter Veterans Administration hospitals have prepaid hospital insurance. They cannot properly sign a statement that they are unable to pay, and, besides, why does not the Veterans Administration try to collect that money?"*

Prepaid hospital insurance and a veteran's "ability to pay" are not antithetical or inconsistent. At the very most, medical insurance applies only to that part of medical care covered by the policy. It seldom covers all hospital costs, and it does not pretend to cover all costs in related areas. For example, hospitalization insurance does not usually cover all medical costs, physicians' fees, examinations, and so on, all of which are included in Veterans Administration hospital care.

Effort by the Veterans Administration to recover hospital insurance payments is not based on the belief that the insurance policy indicates a veteran's ability to pay. It is based on the Veterans Administration's authority to prescribe limitations for non-service-connected hospitalization. And, of course, should the Veterans Administration receive such payment, not one cent comes from the veteran or his family. Collection is made from a third party, the insurance company, or other person who is liable for such costs. The sheer truth is that the Veterans Administration is collecting such payments wherever and whenever actual liability exists. During the fiscal year 1952, the Veterans Administration secured for the federal government approximately \$3,050,000 in reimbursement for hospital care furnished veterans with non-service-connected disabilities, for which hospital care third parties were liable in contract or tort. But Veterans Administration collections of this sort in no way indicate the slightest departure from the lawful policy of dealing with patients having non-service-connected disabilities.

(I) *"I hear that . . . if the Veterans Administration would toss out all patients with non-service-connected disability and admit to its hospitals only service cases millions of dollars would be saved and the veterans with non-service-connected disability could pay for their treatment in private hospitals just as anyone else."*

Those who subscribe to the above opinion err in several major premises. The Veterans Administration could not, even if it would, toss out all patients with non-service-connected disability. The law prescribes the eligibility requirements of veterans for admission to Veterans Administration hospitals, for the treatment both of service-connected and of non-service connected disabilities. The

Veterans Administration administers the law, and its hospital program is predicated on its provisions. Only Congress can change the law, not the Veterans Administration. Assuming, however, that Congress did change the law and that veterans with non-service-connected disability were in fact barred from Veterans Administration hospitals, it does not follow that millions of dollars would be saved the American taxpayer. The bulk of such patients, which includes the tuberculous and neuropsychiatric patients, those with long-term chronic cases, and the indigents, would either have to be treated at public expense in other public-supported hospitals, with no consequent "savings of millions," or would receive no care at all, with consequent economic loss to the community, state, and nation.

(J) *"I hear that . . . Veterans Administration hospitals are full of a lot of 'frills' that produce useless 'coddling' of patients. Veterans Administration hospital methods should be streamlined in accordance with best medical opinion in the U. S."*

It has generally been found that those who hold that Veterans Administration hospitals are full of a lot of "frills" are uninformed as to the medical reason for and uses of the so-called frills. These so-called frills, when investigated, prove to be approved and accepted procedures in modern medicine, which has made giant strides in recent years. As for the Veterans Administration's hospital methods, the close collaboration of the hospitals with this country's leading medical schools has resulted in a practice of medicine in Veterans Administration hospitals that has received widespread commendation. Modern hospital treatment includes many items not formerly thought indispensable or even practicable.

(K) *"I hear that . . . Veterans Administration hospitals are an opening wedge for socialized medicine. The overwhelming majority of its patients with non-service-connected disability are depriving private physicians of legitimate fees."*

It would be well at this point to review the constitution of the Veterans Administration's hospital patient population as itemized under (A) above. Of the 104,820 patients, 14% were tuberculous, 48.3% were psychotic, 3.7% had other psychiatric disorders, and 4.7% had neurological disabilities. Well over a third of the tuberculous patients had been on the hospital rolls for more than 1 year, well over a third of the psychotic patients for more than 10 years, and over 50% of all patients hospitalized on Jan. 31, 1953, had already spent more than a year on hospital rolls as Veterans Administration patients. Further, nearly half of the World War I patients (hospitalized for all causes) had been on hospital rolls as Veterans Administration patients for more than 5 years and nearly one-fourth for more than 15 years. Over 47% of the World War II patients had been on hospital rolls for more than a year and 23% more than five years. I leave it to the judgment of the reader whether these patients could be expected to defray the costs of such long periods of hospitalization. It is reasonable to assume that were they excluded from the Veterans Administration hospitals they would turn elsewhere for treatment at public expense, burdening beyond their capacities the already overtaxed

state, city, and county institutions. Further, I believe it unrealistic to compare Veterans Administration medicine with socialized medicine as it exists in some countries.

(L) *"I hear that . . . what the Veterans Administration is really doing is hiding behind the law."*

This is a statement of opinion that is negative, unrealistic, and untrue. Properly stated: The Veterans Administration is obliged to and intends to obey the law at all times. It executes the law that was promulgated for it to follow. The Veterans Administration cannot, in the nature of things, "hide" behind anything or anybody, so far as public knowledge of its duties and its accomplishments is concerned. Ultimately, it is for the people of the United States to say what the Veterans Administration shall do; the Veterans Administration is merely the servant of the people to carry out their mandates as expressed in law.

(M) *"I hear that . . . veterans and their wives and children get free medical care in Veterans Administration hospitals. I have heard of cases in which the wives have their babies and the children have their tonsils removed at the taxpayer's expense."*

That just is not true and never has been. Wives, children, dependents, and relatives of veterans cannot and do not get medical service from the Veterans Administration, unless they themselves are eligible in their own right by reason of the fact that they themselves are veterans. The women patients being treated by the Veterans Administration are women veterans, and for them pregnancy per se does not entitle them to hospitalization by the Veterans Administration.

(N) *"I hear that . . . getting into a Veterans Administration hospital is a matter of favoritism. I have heard of a sick veteran waiting weeks and weeks to get into a hospital, whereas I have seen veterans from this same town admitted, and they did not look a bit sick to me."*

Admittance to a Veterans Administration Hospital is regulated by rules set up under the law. Emergency cases get top priority; service-connected cases get first call. Patients with non-service-connected cases must be legally eligible for treatment, must need hospital treatment, must be unable to pay for necessary care (permissibly evidenced by sworn statement of such inability), and must follow priority rules for admission. Patients who do not need treatment cannot be admitted except those who are brought in for a period of observation and examination for adjudication of claims. During the fiscal year of 1953, nearly a million applications for hospital care were received; 468,349 were admitted.

(O) *"I hear that . . . there is no humanity in Veterans Administration hospitals. Patients are handled like robots. I heard of a patient, seriously ill with tuberculosis, sent miles away for treatment instead of to the Veterans Administration hospital close to home where his wife and children could visit him. It is not humane."*

On the contrary, it is humane and sensible, too. The humane thing is to give this patient the best possible treatment for tuberculosis and to return him to his home and family in the shortest time possible. Sometimes a special-

ized tuberculosis hospital remote from his home is the answer to a problem of this sort; however, when it is medically feasible, the invariable Veterans Administration rule is to hospitalize veterans as close as possible to where their families live.

(P) *"I hear that . . . Veterans Administration hospitals are more like country clubs than places for sick persons. Why all this tennis and golf, all this basket weaving and shop work? I thought that the aim is to cure the patient."*

The aim is to cure the patient and to do this with the utmost speed consistent with good medical practice. In Veterans Administration hospitals, we treat the "whole man," not just the disease. Games, shop work, and other programs are done on doctors' prescriptions; in short they are part of various therapies aimed at helping to make the patient ready for discharge at the earliest possible time. "Getting well" involves far more than lying in bed and taking medicine. Veterans Administration medicine is modern medicine at its best. With thousands clamoring for admission, what possible motive could the Veterans Administration have for extending care unnecessarily?

(Q) *"I hear that . . . one veteran with a service-connected disability is treated by his private doctor, while another fellow is not. I heard of a veteran with a service-connected disability who went to his own hometown doctor, and then when the bill came due, had to pay out of his own pocket. Yet the other veteran did not pay. Does this make sense?"*

It is a matter of following simple, easy-to-understand rules. If a veteran with a service-connected disability needs medical treatment and treatment at a Veterans Administration facility is not convenient for the Veterans Administration, or for him, he may be granted permission to go to his own private physician, if he applies beforehand for the Veterans Administration's authorization. If a veteran does not apply to the Veterans Administration before going to his own doctor for treatment, he does not bring himself within the rules and risks paying out of his own pocket for the unauthorized private treatment.

(R) *"I hear that . . . Veterans Administration doctors are below par professionally. There is no incentive for a young doctor who is ambitious and eager to advance in his profession if he joins the Veterans Administration medical staff."*

Those who hold this view manifest an astounding ignorance of the professional staff of the Department of Medicine and Surgery of the Veterans Administration and the opportunities that are afforded its members. As of the last day of the fiscal year 1953, 2,210 physicians were receiving residency training under medical school supervision at 73 Veterans Administration hospitals and in 1 Veterans Administration mental hygiene clinic. There were 65 different medical schools affiliated with 85 Veterans Administration hospitals. The faculty members and other leaders in the profession not only share in the treatment of the Veterans Administration's patients but also engage in the education and research programs in operation throughout the Veterans Administration hospital system. Postgraduate and in-service training programs provide ample opportunities for educational and profes-

sional advancement. In those Veterans Administration hospitals situated at a distance from medical schools and institutions, leaders in medical and related fields of health have been able to bring to the staffs of these hospitals by lecture programs information concerning recent developments in a wide variety of fields of specialization. In fact, the success of Veterans Administration medicine has been closely related to the education and research activities, all essential factors in providing the veteran patient with the best possible medical treatment and hospital care. There is no better professional opportunity for a young, ambitious physician than in Veterans Administration medicine. It is not a get-rich-quick opportunity but one to grow by serving, to progress by accomplishment.

(S) *"I hear that . . . research into atomic medicine and other things out of place in a hospital are going on at the Veterans Administration. Why all this emphasis on isotopes? Why not do the things that actually help sick patients get well?"*

Atomic medicine is not out of place in a Veterans Administration hospital. Radioisotopes are used in clinical diagnosis and treatment as well as in medical research. The medical profession has learned their value in thyroid and suspected brain tumor cases, to mention only two of a large array of physical ailments susceptible to this new diagnostic and therapeutic procedure. Veterans Administration atomic medicine research is in the van of this kind of medical advance. In fact, the Veterans Administration is operating some 27 radioisotope laboratories. They complement the investigations of the Atomic Energy Commission. In addition, every advance made in a Veterans Administration laboratory is available to the entire medical profession, as is every other advance in other fields. It would be difficult to refute the proposition that Veterans Administration medicine has furthered inestimably general medical practice, or that it should do so.

(T) *"I hear that . . . in Veterans Administration hospitals they practice on patients with young and untried doctors who have insufficient experience."*

That is completely untrue. Resident physicians in training for specialties are the backbone of any well-run hospital. All are graduate doctors. All have completed an internship. All have been recommended by dean's committees in the foremost medical centers in the United States. Young, well-qualified, and ambitious physicians gladly enter Veterans Administration medicine because it puts them in daily touch with the latest and best in treatment and the most modern medical concepts and practice.

(U) *"I hear that . . . in a Veterans Administration mental hospital veterans disappear for good. They are just kept there and are never cured."*

It is realized that the length of hospitalization of a patient afflicted with a mental disorder may extend over a considerable period of time. I have pointed that out elsewhere in this article. Nevertheless, through the efforts of all the persons that comprise the hospital teams of Veterans Administration hospitals, large numbers of patients are being rehabilitated successfully to permit them to return to their families. To indicate the extent to which the Veterans Administration is succeeding in helping the psychotic patients and those afflicted with other psychi-

atric conditions, it is interesting to note that 2,700 of the former and 2,800 of the latter group were discharged from Veterans Administration hospitals during the last quarter of 1952. This evidences real accomplishment—worth far more to the country than it costs.

(V) *"I hear that . . . the Veterans Administration lets mental patients go home when the family insists on it—then later the released mental patient kills somebody. Why do Veterans Administration hospitals release persons like that to become public menaces?"*

A patient afflicted with a mental disorder cannot be legally kept in a Veterans Administration hospital against his will unless he has been legally committed by an authority of proper jurisdiction. A person who has not been committed is a voluntary patient; if he insists on leaving, the Veterans Administration medical authorities cannot legally detain him. However, every effort is made to collaborate with family and civil officials to insure commitment when deemed necessary for the safety of the patient or the public. Veterans Administration hospitals are not asylums.

(W) *"I hear that . . . Veterans Administration hospitals stage 'raids' in their local areas to snatch away doctors and nurses who may be badly needed where they are."*

The Veterans Administration considers its hospitals as integral parts of the communities in which they are located and, as such, strives for a mutual spirit of good will and cooperation between Veterans Administration and non-Veterans Administration medical institutions in any given area. The "raiding" of local areas as a method of obtaining doctors and nurses for the staffing of new Veterans Administration hospitals is contrary to the Veterans Administrations hiring policy, and any such charge is not supported by the facts. The Veterans Administration's hospital system is national in scope. Doctors and nurses who express their interest in serving with the Veterans Administration indicate their geographical preferences for assignments. Vacancies are filled by transfers from other stations and by new appointments, meeting the desires of the new applicants as to location insofar as it is possible.

(X) *"I hear that . . . a lot of these patients with so-called non-service-connected disability in Veterans Administration hospitals are alcoholics who are admitted just so they can 'sober up.'"*

The same principles and procedures govern the admission of these veterans to Veterans Administration hospitals as apply to all veterans. When it is medically determined that a veteran is in need of hospital treatment, he is admitted, if he is legally entitled to Veterans Administration care and a bed is available. Unless he meets all criteria, he is not admitted.

(Y) *"I hear that . . . Veterans Administration doctors are older physicians who could not succeed in private practice and join the Veterans Administration for snug berths."*

This is the opposite side of the "green young doctor" canard. It is, of course, just as false. As of June 30, 1953, 1,684 out of a total of 4,160 full-time Veterans Administration doctors held memberships in various of the several

specialty boards. The progressive medical atmosphere of the medical department of the Veterans Administration that pervades through all of its echelons completely refutes this contention.

(Z) "I hear that . . . veterans whose illness has nothing to do with their service in the armed forces are no more entitled to free Veterans Administration hospitalization than anyone else. After all, we are all citizens. Why should the Veterans Administration discriminate in favor of one group?"

The Veterans Administration discriminates in favor of neither group, veteran or nonveteran. It applies the laws as they have been enacted by Congress, which express but the will of the people as made manifest through their elected representatives. From colonial days, the citizenry of this country have offered its resources to the veterans of this nation and have expressed its interest in meeting their medical needs. Until this concept of the people is relinquished through legislative expression, the Veterans Administration will continue to administer the laws as they exist today.

I think enough has been written, although briefly, to sustain my thesis that many prevalent notions about Veterans Administration medicine have no basis in fact and contribute nothing to better public understanding of the very real problems, the truly hard labors, and the demonstrable achievements of the Department of Medicine and Surgery of the Veterans Administration. In bringing this topic to the attention of my fellow physicians, I am animated by the hope that all of us may join hands professionally in an endeavor, if not to wipe out these and other misconceptions, at least to help minimize their ill-effects as far as we may. To silence the malicious rumor monger is an impossible task but to shine a little truthful light into dark corners, where darkness exists only because no one has yet bothered to come with a light, it seems to me, offers a real opportunity to medical men of good will everywhere. And the gainers will be the veterans, the hospital patients, the physicians, and all the tax-paying citizens of our country.

COMMENT ON ADMIRAL BOONE'S ARTICLE

In May, 1953, the foregoing article was submitted for publication by Adm. Joel T. Boone, Chief Medical Director of the Veterans Administration. On May 27 the article was rejected, since it was felt that it contained a considerable amount of information already well known to the medical profession. In addition, the subject of medical care and hospitalization of veterans with non-service-connected disabilities was scheduled for consideration by the Board of Trustees and the House of Delegates of the American Medical Association at its annual meeting to be held in June. The manuscript has again been submitted by Admiral Boone, with the request that it be published in the light of the new policy, with respect to veterans' medical care, which was established by the Association at its meeting last June.

In view of the controversial nature of some of the items discussed, Admiral Boone's article is published as submitted, together with a critique of some of the items discussed. This critique was prepared by those who are closely associated with the interpretation of the policies of the American Medical Association concerning medical care for veterans.—ED.

The above article was rejected for publication in May, 1953. Since that date, and following the action of the House of Delegates in June, 1953, with respect to vet-

erans' medical care, Admiral Boone and others are reported to have protested the action of the Editor in refusing publication of his manuscript. Copies of the article were sent to members of the House of Delegates of the American Medical Association and to other officers and officials. In addition, the Association was criticized before committees of Congress for its action. At the request of the author of the article, it was published in the appendix of the Congressional Record by Mrs. Edith Nourse Rogers, chairman of the House Committee on Veterans Affairs.

Despite the fact that the article has comparatively little bearing on the basic elements involved in the present position of the Association with respect to veterans medical care, it seems well to discuss it briefly to dispel the confusion that it may create.

It is possible that the alleged "misconceptions" referred to in the article do exist in some quarters. However, it is certain that the majority of them are not prevalent in medical circles. For the most part, they either are the result of statistical manipulations or consist of issues that have been amplified in order to provide a medium for publicizing well-known information concerning the Veterans Administration and its medical program. In his paper Admiral Boone poses 26 questions that he professes to answer. In some instances his statements are completely accurate and relate to matters that have never been questioned by the medical profession. In other instances, however, his remarks are more confusing than explanatory. It is felt that 10 of the 26 points raised require further explanation.

To simplify this analysis, the various points in question will be repeated.

(A) "I hear that . . . 90% of patients in VA hospitals (in some statements the percentage used was 80% or two-thirds) are being treated for non-service-connected disabilities."

In discussing this statement a series of statistics are presented which are intended to minimize the extent of non-service-connected medical care that is currently being provided by the Veterans Administration.

At the outset it should be recognized that as in all discussions of this type, irresponsible statements have been made by persons on both sides of the question. These most frequently occur when statistics are involved. In most instances in which substantial variations have occurred they have resulted from the fact that the persons concerned have been talking about entirely different things. As an example, the figures presented by Admiral Boone under item A refer to the number of patients in Veterans Administration hospitals as of a given date, i. e., Jan. 31, 1952. There can be no question but that the figures here presented and the percentage of service-connected disabilities (35.6%) are completely accurate. It is not sufficient, however, to consider only these figures.

Persons who have referred to the non-service-connected load as consisting of from 80 to 90% of the total Veterans Administration medical program were undoubtedly speaking in terms of the total number of patients admitted or discharged in a given year. According to the figures of the Veterans Administration its admissions for

the calendar year 1951 totaled 509,720. Of this number, 84.6% were non-service-connected cases. It is clear, therefore, that Admiral Boone and the persons who have alleged a higher percentage of non-service-connected cases may both be correct, depending upon whether they were talking about total admissions for a given year or the patient load as of a given day.

In answer to this same question an attempt is made in the article to explain away the remaining 64.4% of the VA patient load (non-service-connected cases) as of a given day: Jan. 31, 1952. It is indicated that 11.4% of these patients were veterans discharged from military service with service-connected disabilities who are now receiving care for other disabilities. Falling within this group are those veterans who have some type of service-connected disability for which hospitalization is not now required. These men have contracted some additional disease or disability completely unrelated to military service for which they are now being hospitalized. It is obviously unfair to refer to the disabilities of this group as service connected. The remaining war veterans (52.4%) are acknowledged in the article as being treated for non-service-connected injury or disabilities.

As indicated, some of these persons are suffering from tuberculosis, neuropsychiatric disorders, or chronic diseases. They are, nevertheless, of non-service-connected origin. In addition, some may or may not be entitled to receive a "pension." The diseases or disabilities for which medical care is provided nevertheless have no relationship to military service. The fact that a limitation of income is imposed before a pension can be paid is of importance only as one element in determining whether a veteran may or may not be able to pay the cost of his own medical care.

(B) "*I hear that . . . veterans with non-service-connected ailments sign a pauper's oath to get into a Veterans Administration hospital, and the Veterans Administration makes no effort to check for fraudulent oaths.*"

As has been stated on many occasions in discussing the position of the Association in this matter, it is not our desire to comment on alleged maladministration by the Veterans Administration, the ability or inability of individual veterans to pay, or the extent to which the use of the Veterans Administration Form 10-P-10 is being abused. It should be noted on this point that recently the Veterans Administration devised a new form and promulgated new regulations that will require the veteran to supply additional information regarding his financial status. This change in itself is an admission that more stringent regulations were necessary.

There has been no change in the basic law since the date the article in question was written. Therefore, questions are bound to be asked as to the source of the authority of the Veterans Administration, which they have not seen fit to exercise during the many years since this legislation was originally enacted.

(D) "*I hear that . . . too many hospitals have been built by the Veterans Administration. Right now there are more than are needed to serve eligible veterans.*"

In answering this contention, reference is made to the number of veterans currently awaiting admission to Veterans Administration hospitals. In this connection it should be noted that as of Nov. 30, 1953, there were 17,512 veterans awaiting admission to VA installations. Of this number only one was suffering from disabilities of service-connected origin. Thus, in determining whether too many hospitals have been built by the Veterans Administration, it is necessary to consider the size of existing facilities, the number of patients with non-service-connected cases receiving medical care, and the patient waiting list, in the light of the original purpose and intent of the law.

There can be no doubt that the primary mission of the medical program of the Veterans Administration is to care for veterans with service-connected disabilities. Medical care and hospitalization was authorized only for patients with non-service-connected cases because of a surplus of hospital beds in 1923. The basic legislation authorizing the present program stipulates that medical care and hospitalization in non-service-connected cases shall be provided only within the limits of existing facilities. For many years the number of Veterans Administration hospital beds has been more than adequate to take care of the service-connected patient load. Consequently, VA hospitals that have been built during the past several years and those in the planning state must be intended primarily for non-service-connected medical care. Anyone interested, therefore, in discussing veterans' medical care, within the framework of existing law, is justified in the statement that too many VA hospitals have been built.

(F) "*I hear that . . . patients are kept in Veterans Administration hospitals far longer than necessary, longer than the normal stay in a non-Veterans Administration hospital.*"

While it has not been alleged by the medical profession that patients are kept in Veterans Administration facilities longer than necessary, it is proper to compare the length of stay in VA facilities with the length of stay in nonfederal facilities. According to the figures of the Veterans Administration, the average VA hospital stay for a patient receiving general medical and surgical care is 30.4 days, compared to 7.5 days for a patient with similar disabilities in a civilian hospital. In private hospitals during a year's time each bed is utilized to provide care for 35.4 patients, compared to each VA general medical and surgical bed, which provides care for only 8.9 patients.

(H) "*I hear that . . . some patients who enter Veterans Administration hospitals have prepaid hospital insurance. They cannot properly sign a statement that they are unable to pay, and, besides, why does not the Veterans Administration try to collect that money?*"

Much has been said concerning the right and authority of the Veterans Administration to recover private health insurance benefits to which hospitalized veterans are entitled. As has been indicated before, the administrative practice of the Veterans Administration in accepting for hospitalization veterans suffering from non-service-connected disabilities who have prepaid health insurance is, to say the least, difficult to rationalize.

Administrative regulations authorizing the collection of such benefits by the Veterans Administration are inconsistent with previous pronouncements that it is not possible to investigate the statement of the veteran concerning his inability to pay hospital expenses. Either this contention is true and his statement must be accepted without question or the authority cited in Section 6 of Public Law No. 2, 73rd Congress, is sufficient to permit a more complete determination of a veteran's actual ability to pay.

By interesting itself in this one particular aspect of the veteran's financial status, the Veterans Administration has, in effect, evoked a limited means test. If the desire of the Veterans Administration is really to mitigate the financial burden imposed on the taxpayers of their country by the operation of the Veterans Administration hospital program, it would seem to be more easily accomplished by adherence to the original intent of the congress, i. e., to limit hospital care to veterans with service-connected disabilities and to veterans with non-service-connected disabilities who are truly unable to pay for their care and for whom beds are available.

- (I) "*I hear that . . . if the Veterans Administration would toss out all patients with non-service-connected disability and admit to its hospitals only service cases millions of dollars would be saved and the veterans with non-service-connected disability could pay for their treatment in private hospitals just as anyone else.*"

While it is true that the Veterans Administration could not on its own initiative eliminate medical care and hospitalization for veterans with non-service-connected disabilities, it is certainly not improper for an individual citizen or for an organization such as the American Medical Association to attempt to effect a curtailment of the present medical care program through appropriate amendments to existing law. Efforts by certain officials of the Veterans Administration to prevent any change in existing legislation is in actuality "lobbying" and highly improper.

With respect to the shifting of the tax burden it is true that the transfer of veteran patients with non-service-connected disabilities from federal to local hospitals might mean an increase in local tax burden. It would, however, also mean a decrease in the national tax burden. Most persons would not quarrel with such a result, since it is generally recognized that, the closer to home tax funds are spent, the more efficiently they are used.

- (K) "*I hear that . . . Veterans Administration hospitals are an opening wedge for socialized medicine. The overwhelming majority of its patients with non-service-connected disability are depriving private physicians of legitimate fees.*"

The suggestion that the present veterans medical care program is an opening wedge for socialized medicine is not without foundation in fact. Consideration of this proposition cannot, however, be properly limited to a discussion of its economic aspects but rather should be enlarged to include consideration of the basic philosophy of the present program. Attention is invited to the state-

ment presented by Dr. Walter B. Martin, President-Elect of the American Medical Association, in his appearance before the committee of the House Veterans' Affairs Committee on July 13, 1953. At that time, Dr. Martin stated, in part:

The gradual expansion and intervention of the federal government into the affairs of local governments and individuals during the past decade has apparently confused some people as to the proper responsibilities of each. Continued federal encroachment into private affairs cannot be advocated logically and consistently by those who, at the same time, voice their opposition to socialism. It is time to reorient our thinking and to recognize the dangers which threaten the foundation of our basic philosophy before we reach the point of no return in terms of collective socialistic planning. It would be unfortunate indeed, if, in our efforts to reward patriotism, we were responsible for the creation of a system of government medicine, against the will of the majority, with its inevitable deterioration in the quality of medical care for veterans and non-veterans alike.

In discussing this point the article attempts to inject an economic motive for the policy of the medical profession. This obviously cannot be done successfully. Doctors who treat VA patients now are paid for their services; doctors who treat state or county welfare patients frequently are not. In other words, the medical profession, as a whole, will lose rather than gain economically by this policy. If all of the patients with non-service-connected conditions are unable to pay, as consistently alleged by proponents of the present program, they will not be able to pay a private physician.

- (L) "*I hear that . . . what the Veterans Administration is really doing is hiding behind the law.*"

The comments made in connection with questions (B) and (I) are also germane to this item.

- (W) "*I hear that . . . Veterans Administration hospitals stage 'raids' in their local areas to snatch away doctors and nurses who may be badly needed where they are.*"

Although it is probably improper to refer to the attempts of the Veterans Administration to acquire additional personnel as "raids," it is nevertheless true that the expanding VA medical program has contributed to an artificial shortage of medical and allied health personnel in some areas. For every increase in federal hospital beds, more medical personnel is needed—physicians, dentists, nurses, laboratory technicians, and others. To maintain training programs at these hospitals, more interns and residents are needed. In setting salary scales for this personnel the federal hospital is not limited by its income. It has no need to observe the prevailing wage scale in the community. It does not need to consider what the patient is able to pay for hospital service. As a result the federal hospital can outbid the nongovernmental hospital for medical and health personnel and for medical trainees. The nongovernmental hospital can meet the federal bid only by increasing the patient's hospital bill.

In this connection it is interesting to note the following statement which appears in the annual report of the Veterans Administration for 1952: "In an attempt to attract qualified personnel, approximately 13,000 brochures de-

scribing VA medical service have been forwarded to individuals and to 1,035 hospitals having approved residency training programs."

As a specific example of local reactions reference is made to a resolution adopted within the last month by the Cook County Board of Illinois, demanding that the draining of health personnel by the VA stop. The resolution was sponsored by Commissioner John J. Duffy, who said that 95% of the nurses trained by Cook County leave for jobs in veterans hospitals and other federal and private institutions.

(Z) "I hear that . . . veterans whose illness has nothing to do with their service in the armed forces are no more entitled to free Veterans Administration hospitalization than anyone else. After all, we are all citizens. Why should the Veterans Administration discriminate in favor of one group?"

"The Veterans Administration discriminates in favor of neither group, veteran or nonveteran. It applies the laws as they have been enacted by Congress, which express but the will of the people as made manifest through their elected representatives."

In reviewing the testimony, comments, and remarks of representatives of the Veterans Administration before congressional committees and in public appearances, it is questionable that they have adhered solely to the role of administrators of the law. Attempts to discredit individuals and organizations that are interested in changing that law through proper and recognized democratic processes are completely unjustified and improper.

As indicated in the initial paragraphs of this critique, it is not the purpose of the medical profession to discuss the veterans medical care program on the basis of the questions posed in Admiral Boone's article. The medical profession is not primarily concerned with alleged maladministration by the Veterans Administration nor is it discussing the Veterans Administration Form 10-P-10, the ability of individual veterans to pay or the number of "chiselers" in VA hospitals. Rather it is imperative that consideration be confined to the really fundamental questions, which include:

1. Just what is the justification for providing "free" medical care to veterans with non-service-connected disabilities?
2. What is the present system doing to the civilian medical teaching program?
3. Is it creating an artificial shortage of health personnel?
4. Is it lowering the standards and increasing the costs of health care for the general public?
5. Is it contributing to an overlapping of federal medical facilities?
6. Is the huge expense and resulting tax burden justified? and
7. Do the veterans of this country really want this type of handout?

The issue involves basic principles that concern not just veterans and physicians but all of the American people. In a nation with a large, growing, and aging veteran population, there must be a clarification of just how far the federal government should go in assuming responsibility for the medical care of those citizens who once wore a military uniform. The ultimate answer will have a vitally important effect on the future health, economic welfare, and social philosophy of the entire nation.

COUNCIL ON PHARMACY AND CHEMISTRY

The following abstracts of recent nomenclature decisions of the Council is authorized for publication.

R. T. STORMONT, M.D., Secretary.

NEW GENERIC AND BRAND NAMES RECOGNIZED BY THE COUNCIL

The Council collaborates with manufacturers in the selection of generic and brand names for marketed drug preparations presented for acceptance and also for new products still under development or clinical trial. The last reports on such names appeared in *THE JOURNAL*, Oct. 31, 1953, page 801, and Dec. 19, 1953, page 1447.

The following abstract lists the generic designation, the chemical name, where necessary for information, and the brand name or names simultaneously recognized for the stated firms. In general, a generic name should bear recognizable relation to the chemical name and conform as closely as consistent with brevity and practicality to existing systems of scientific nomenclature. The chief requirement for a brand name is that it should not be therapeutically suggestive.

The listing of a brand name is not to be construed as indicating Council acceptance of the product itself. Products accepted for inclusion in New and Nonofficial Remedies are announced separately.

ALSEROXYLON for the fractionally purified extract of *Rauwolfia serpentina* (Benth): Rauwiloid (Riker Laboratories, Inc.).

ALSEROXYLON-ALKAVERVIR for a mixture of partially purified extracts of *Rauwolfia serpentina* and *Veratrum viride*: Rauwiloid-Veriloid (Riker Laboratories, Inc.).

AMINITROZOLE for 2-acetyl-amino-5-nitrothiazole: Pleocide (Sharp & Dohme, Division of Merck & Co., Inc.).

AMINOPTERIN SODIUM for the sodium salt of 4-aminopteroyl-glutamic acid.

AZAPETINE for 6-allyl-6,7-dihydro-5H-dibenz [c,e] azepine: Ilidar (Hoffmann-LaRoche, Inc.).

BACITRACIN-POLYMYXIN B for a mixture of bacitracin and polymyxin B sulfate: Polycin (Pitman-Moore Company, Division of Allied Laboratories, Inc.).

BENZATHINE PENICILLIN G for N,N'-dibenzylethylenediamine dipenicillin G: Bicillin (Wyeth Laboratories, Inc.); Permapen (Pfizer Laboratories, Division of Chas. Pfizer & Co., Inc.).

BENZTROPINE METHANESULFONATE for tropine benzohydril ether methanesulfonate: Cogentin Methanesulfonate (Sharp & Dohme, Division of Merck & Co., Inc.).

BUCLIZINE HYDROCHLORIDE for 1-(p-chlorbenzhydryl)-4-(p-tert-butylbenzyl)-diethylenediamine dihydrochloride: Vibazine Hydrochloride (Pfizer Laboratories, Division of Chas. Pfizer & Co., Inc.).

CRYPTENAMINE ACETATE for the acetate of a mixture of ester alkaloids obtained by the nonaqueous extraction of *Veratrum viride*: Unitensin Acetate (Irwin, Neisler & Company).

CYCRIMINE HYDROCHLORIDE for 1-phenyl-1-cyclopentyl-3-piperidino-1-propanol hydrochloride: Pagitane Hydrochloride (Eli Lilly & Company).

ETHAVERINE HYDROCHLORIDE for the ethyl analogue of papaverine hydrochloride, 6,7-diethoxy-1-(3',4'-diethoxybenzyl)isoquinoline hydrochloride: Papetherine Hydrochloride (Lincoln Laboratories, Inc.).

HEXYLCAINE HYDROCHLORIDE for 1-cyclohexylamino-2-propyl benzoate hydrochloride: Cyclaine Hydrochloride (Sharp & Dohme, Division of Merck & Co., Inc.).

IOTHIOURACIL SODIUM for the sodium salt of 5-iodo-2-thiouracil: Itrumil Sodium (Ciba Pharmaceutical Products, Inc.).

LAUDESIUM METHYLSULFATE for Decamethylene- α , ω -bis-[1-(3',4'-dimethoxybenzyl)-1,2,3,4-tetrahydro-6,7-dimethoxy-2-methyl-isoquinolinium methosulphate]: Laudolissin Methylsulfate (E. Fougera & Company).

METHOXSALEN for 8-methoxypsoralen: Oxsoralen (Paul B. Elder Company).

METHSCOPOLAMINE BROMIDE for epoxytropine tropate methylbromide: Pamine Bromide (The Upjohn Company).

NORTESTERIONATE for 19-nortestosterone cyclopentylpropionate: Nortestonate (The Upjohn Company).

PIPERAZINE CITRATE: Antepar Citrate (Burroughs Wellcome & Company, Inc.).

RESERPINE for the pure form of that alkaloid as derived from *Rauwolfia serpentina* (Benth): Serpasil (Ciba Pharmaceutical Products, Inc.).

SODIUM RADIO-IODIDE (I^{131}) for the sodium salt of radio-active iodine having that atomic number.

STREPTODUOCIN for a mixture of equal parts of streptomycin and dihydrostreptomycin sulfates: Distreptocin (Eli Lilly & Company); Distrycin (E. R. Squibb & Sons); Duostrep (Sharp & Dohme, Division of Merck & Co., Inc.).

TRIMETHAPHAN CAMPHORSULFONATE for *d*-3,4-(1',3'-dibenzyl-2'-ketoimidazolido)-1,2-trimethylenethiophanium *d*-camphorsulfonate: Arfonad Camphorsulfonate (Hoffmann-LaRoche, Inc.).

VIOMYCIN SULFATE for the sulfate salt of an antibiotic produced by selected strains of an actinomycete to which the names *Streptomyces puniceus* and *Streptomyces floridiae* have been applied: Vinactane Sulfate (Ciba Pharmaceutical Products, Inc.); Viocin Sulfate (Pfizer Laboratories, Division of Chas. Pfizer & Co., Inc.).

ZINCHLORUNDESAL: Salundek (New) (Wallace & Tiernan Inc.).

COUNCIL ON FOODS AND NUTRITION

ACCEPTED FOODS

The following products have been accepted as conforming to the rules of the Council.

JAMES R. WILSON, M.D., Secretary.

Prescription Products Division of The Borden Company, New York.

Mull-Soy, Powdered

Ingredients: Soy flour, soy oil, sucrose, dextrose, calcium phosphate, soy lecithin, and salt.

Analysis (submitted by manufacturer).—The following analyses are for both powder and reliquefied.

	Powder, Reliquefied,*	
	%	%
Total Solids	96.5	12.8
Moisture	3.5	87.2
Ash (Minerals)	5.4	0.7
Including:		
Calcium	1	0.13
Phosphorus	0.9	0.11
Iron	0.003	0.0004
Soy Fat	30	4
Soy Protein	24	3.1
Carbohydrate (available)	35.9	4.5
Crude fiber	1.2	0.2

* Reliquefied: 1 level tablespoonful (8.4 gm., 43.5 calories) Mull-Soy, Powdered, and 2 fl. oz. of water.

Calories.—5.2 per gram; 43.5 per level tablespoonful, 20 per reconstituted fluid ounce.

Use.—As a hypoallergenic food for infants, children, and adults suffering from milk allergies.

Comstock Canning Corporation, Newark, N. Y.

Comstock Brand Dietetic Pack Peas and Carrots

This product consists of peas (Famous variety) and carrots (Red Cored Chantenay) packed in water without any added salt.

Analysis (submitted by manufacturer).—Total solids 9.2%, moisture 90.8%, ash 0.29%, fat extract 0.2%, protein 2.1%, crude fiber 1.4%, available carbohydrate 5.1%, and sodium 10.1 mg./100 gm.

Calories.—0.30 per gram; 8.5 per ounce.

Use.—For use in low sodium and other therapeutic diets.

H. J. Heinz Company, Pittsburgh.

Heinz Junior Soup, Split Peas, Vegetables, and Ham

Ingredients: Ham stock, split peas, smoked ham, potatoes, carrots, whole milk powder, wheat flour, celery, salt, dehydrated onion, and sufficient water to prepare properly.

Analysis (submitted by manufacturer).—Total solids 18.03%, moisture 81.97%, ash 1.31%, fat (by acid hydrolysis) 2.15%, protein ($N \times 6.25$) 3.97%, crude fiber 0.23%, total sugar as sucrose 1.35%, natural reducing sugar 0.62%, acidity (as acetic) 0.13%, salt 0.84%, and starch 9.02%.

Vitamins and Minerals	Per 100 Gm.
Vitamin A activity.....	116.0 I.U.
Thiamine	92.0 mcg.
Riboflavin	48.0 mcg.
Ascorbic acid	1.1 mg.
Niacin	0.51 mg.
Calcium	29.0 mg.
Phosphorus	87.0 mg.
Iron	0.66 mg.
Copper	0.11 mg.

Calories.—0.78 per gram; 21.8 per ounce.

Use.—For use in the feeding of older infants and young children.

Armour and Company, Chicago, packer.

Gerber Products Company, Fremont, Mich., distributor.

Gerber-Armour Strained Liver and Bacon

This product is made from meats (trimmed of fat, sinews, and connective sheaths) with added salt, prepared under inspection of the Meat Inspection Division of the U. S. Department of Agriculture.

Analysis (submitted by manufacturer).—Total solids 22.7%, moisture 77.3%, ash 1.6%, fat 6.0%, protein ($N \times 6.25$) 13.3%, carbohydrates 1.8%, crude fiber 0.06%, and salt 0.4%.

Vitamins and Minerals	Mg. per 100 Gm.
Thiamine	0.050
Riboflavin	2.31
Niacin	6.70
Pyridoxine (Vitamin B ₆).....	0.264
Phosphorus	240
Calcium	20
Iron	37

Calories.—1.17 per gram; 33.2 per ounce.

Use.—For use in the feeding of infants, convalescents, and others requiring a soft diet.

Gerber-Armour Chopped Liver and Bacon

This product is made from meats (trimmed of fat, sinews, and connective sheaths) with added salt, prepared under inspection of the Meat Inspection Division of the U. S. Department of Agriculture.

Analysis (submitted by manufacturer).—Total solids 29.1%, moisture 70.9%, ash 1.6%, protein 19.4%, fat 6.8%, crude fiber 0.06%, carbohydrates 1.3%, and salt 0.2%.

Vitamins and Minerals	Mg./100 Gm.
Thiamine	0.0483
Riboflavin	2.17
Niacin	10.8
Pyridoxine (Vitamin B ₆).....	0.417

THE TREATMENT OF GASTRIC ULCER

The two most controversial points regarding the treatment of gastric ulcer still revolve about the question whether medical or surgical treatment is best and whether all ulcers of the stomach in contrast to those of the duodenum should be considered potentially malignant. The questions are interrelated. The first controversy has been raging for over 50 years chiefly because no general rule can be applied to all gastric ulcers. In the last analysis the treatment of choice depends on the individual findings and to a certain extent on the knowledge and skill of the doctor treating the patient.

Dragstedt¹ has reviewed the question whether gastric ulcer is caused by hyperfunction or dysfunction of the gastric antrum. He draws attention to important differences between gastric and duodenal ulcers. Although a preponderance of patients with duodenal ulcer are men, the sex distribution of those with gastric ulcer is about equal. Stigmas of nervous tension are frequently present in those with duodenal ulcer and frequently absent in those with gastric ulcer. Swynnerton and Tanner² state that duodenal ulcers occur predominantly in young adults with thick hypersecreting gastric mucosa and gastric ulcer in middle-aged persons with normal or thinning mucosa and normal or decreased gastric acidity. Excision of the pyloric antrum in patients with duodenal ulcer is followed by a gastrojejunal ulcer, but in patients with gastric ulcer this operation is followed by healing. Although this is in harmony with the view that gastric ulcer may be due to antral hyperfunction and although in patients with gastric ulcer gastric hypersecretion results in excessive and prolonged liberation of the gastric secretory hormone gastrin, Dragstedt concludes that we

still do not have enough evidence that a hypersecretion of antral origin is present in all patients with gastric ulcer.

Orellana³ reported that medical treatment was effective in 84% of a large series of patients with gastric ulcer and that in the 16% requiring operation the mortality was high. Swynnerton and Tanner, on the other hand, concluded that the healing of gastric ulcers by medical treatment was followed by recurrence in 75%, the incidence of recurrences being higher in those under than in those over 50 years of age. They stated that for economic and clinical reasons there has been a tendency to treat chronic gastric ulcers surgically, and in 80% of their series surgical treatment was successful. They listed as absolute indications for operation (1) perforation, (2) some cases of gastric hemorrhage, (3) obstruction with hour glass deformity or pyloric stenosis, and (4) suspected malignancy (which in their opinion included all ulcers of the greater curvature and most prepyloric ulcers), and they considered operation elective for patients in whom medical treatment fails. Partial gastrectomy is the treatment of choice for chronic gastric ulcers, but before it is advised they consider the duration of the disease, severity of the symptoms, presence of intercurrent disease, and operative risk, and they stress the fact that this operation does not prevent the subsequent development of gastric carcinoma.

The differentiation of benign and malignant gastric ulcers is difficult without a biopsy. Boudreau⁴ stated that judgments based on the location of the lesion have proved unreliable because both benign and malignant lesions have been found in all areas of the stomach. The size of the lesion cannot be depended on for diagnosis, but carcinoma must be suspected if after three or four weeks of medical treatment the crater as seen roentgenologically increases in diameter or even if it fails to become smaller. The age of the patient is also unreliable as a criterion, because ulcers in patients over 50 are not necessarily malignant and those in patients under 50 are not necessarily benign. Hemorrhage and perforation are much commoner in patients with benign than in those with malignant ulcers. Gastroscopy and improvements in cytological diagnosis offer hope for more accurate diagnoses. There is a growing belief that benign ulcers do not undergo malignant degeneration as formerly thought but that ulcers found to be malignant were malignant from the start. Boudreau's study shows the fallibility of absolute dependence on any clinical feature in the differential diagnosis of benign and malignant gastric ulcers, and the authors conclude: "the proper diagnosis when possible can be arrived at only by the use of many clinical findings each of which is of uncertain significance but whose combined value may permit a reasonably accurate decision." Eusterman⁵ in commenting on this conclusion said, "In contrast to the contention of some surgeons that there is at least a 35% error in distinguishing a benign from a malignant ulcerating gastric lesion is the recent opinion of several authorities that such error should not exceed 6%, provided all symptoms and signs,

together with the effect of adequate medical treatment in doubtful cases, are properly evaluated by those with specialized skill."

The unceasing flow of papers on this subject shows that there is no unanimity concerning the effectiveness of any one method of treatment. Nevertheless, nearly all gastric ulcers will respond to rest in bed, regular meals, and drugs to suppress or neutralize gastric acidity. The dictum that all gastric ulcers should be removed when the diagnosis is established is rapidly losing its authority, as most internists and surgeons favor at least a preliminary trial of medical management during a few weeks or months and some favor continuing medical treatment. Gastric ulcers of the pylorus or the distal half of the stomach usually can be readily resected without a high mortality risk or troublesome postgastrectomy symptoms. Juxta-esophageal or high lying gastric ulcers are less readily resected; therefore, they are frequently given longer periods of trial with a medical regimen or treated surgically by resection of the distal half of the stomach, leaving the ulcer in place. Total or near total gastrectomy is usually employed only when failure of healing follows conservative operation and malignancy is suspected. Whenever prolonged medical treatment is employed a regular follow-up program of roentgenologic and other studies should be instituted lest early evidence of development of carcinoma be overlooked.

DETECTION OF HEPATIC METASTASES

The presence or absence of liver metastases is often of major importance in determining the treatment or the prognosis of malignant neoplastic disease. A method for detecting and localizing hepatic metastases by radioactive isotopes has recently been described by Stirrett and his associates.¹ In their hands, this method has proved to be more reliable than needle biopsy and liver function tests, the only laboratory procedures currently available to the clinician.

The method consists of the use of radioactive iodinated human serum albumin as the tracer agent and of a scintillation counter to detect gamma radiation from the radioactive iodine (I^{131}). The patient receives a single intravenous dose of 300 μ c of the radioactive albumin, and 24 hours later a survey is made at coordinate points over the thorax and abdomen. The values obtained are expressed in terms of per cent of an arbitrarily chosen reference point. A value at a particular point higher than that which would be expected from results obtained in a series of 20 carefully selected control patients is interpreted as indicating a neoplastic growth.

Stirrett and his associates have reported the results of hepatic radioactive surveys in 240 patients with primary neoplasms. Of these, 187 were shown to be free of metastases by inspection and palpation of the liver at surgery, by microscopic examination of biopsy specimens, and by clinical evaluation. Preoperative hepatic radioactivity surveys showed increased foci of activity in six of these patients. It was subsequently shown that two of these six had a large benign gastric ulcer, two had ascites, and two

showed no evident pathological area other than the primary neoplasm. In the remaining 53 of the patients with known neoplasms, hepatic metastases were demonstrated at laparotomy, though in only 11 was hepatic involvement suspected on clinical grounds. In 49 of these patients, the hepatic survey revealed foci of increased radioactivity. Autopsy studies in 24 of these patients showed that the location and extent of these foci corresponded to the degree of liver involvement. Liver function tests were performed in 28 patients who were subsequently shown to have metastases to the liver. In 16 of these patients the results of all tests used were within normal limits, while in 26 of the 28 patients, the radioactive survey revealed correctly the presence of metastases.

Control surveys were done on 28 patients with benign liver disorders. Abnormal results were obtained in six of eight patients with cirrhosis and ascites and in two of six patients with acute hepatitis. Normal readings were obtained in these two patients after the acute phase of the hepatitis had subsided. Normal readings were also obtained in 14 patients who had cirrhosis without ascites.

The authors feel that the usefulness of this method may not be limited only to liver surveys, since in 11 patients foci of increased activity were found elsewhere and were shown by subsequent operation or autopsy to overlie metastatic lesions. While the method was occasionally of value in detecting recurrent neoplasms, it did not appear to be of value in detecting primary neoplasms, since in only six patients was increased activity observed over the primary site, and all six of these patients were shown to have large neoplasms with local extension of the tumor.

Tissue from primary neoplasms often showed no more activity than that of adjacent normal tissue, whereas the activity in metastases averaged 31% more than that of normal adjacent tissue. Apparently, the extent of the hepatic involvement rather than the histological type determined the degree of increased radiation. The smallest metastases detected by radioactive survey were approximately 2 cm. in greatest diameter. The investigators suggest that the increased concentration of the radioalbumin in metastatic lesions may have some relation to a specific affinity for the compound by the tumor cells or to the increased cellularity and vascularity of the metastatic lesion.

Stirrett and his associates advocate the routine use of hepatic radioactivity surveys in both the preoperative evaluation of all patients with suspected carcinoma and the follow-up examinations of these patients after surgery. They feel this method offers a safe and accurate method of determining the presence of hepatic metastases provided these lesions are at least 2 cm. in diameter and provided the patient is free of ascites, inflammatory processes in the liver, and intra-abdominal inflammatory lesions.

THE PRESIDENT'S PAGE

A MONTHLY MESSAGE

During my recent extended tour of California I had the privilege of taking part in a series of meetings sponsored jointly by local chambers of commerce and medical societies. This was a rewarding experience and one that I wish many other doctors could have shared. I was afforded the opportunity of discussing medico-economic problems with a great number of laymen and of telling the positive story of the American Medical Association's many achievements in public service. The jointly sponsored meetings were held in San Diego, Los Angeles, Pasadena, San Francisco, and Sacramento. Most of these gatherings drew capacity audiences, and about two-thirds of those attending were lay persons.

It was gratifying to find such keen interest in the activities of the medical profession. At the same time I had the impression that the physicians who attended the meetings also enjoyed the opportunity of exchanging opinions and ideas with the businessmen, industrialists, and other professional men who were present. From the standpoint of communications, I believe this is one of the most effective devices for telling the story of American medicine. A word of mouth message is frequently more impressive than one on a printed page. It is a procedure that I wish county medical societies throughout the country could adopt on a periodic basis.

The managers of the chambers of commerce whom I met expressed great satisfaction with the success of the jointly sponsored meetings. They thought the idea was mutually advantageous. It is my personal belief that such joint sponsorship need not be restricted to chambers of commerce; probably equal cooperation could be obtained from Rotarians, Kiwanis clubs, Lions clubs, and other service organizations, as well as from other associations.

One of the chief afflictions among professional and businessmen in our complex society to day is lack of interest in what the other fellow is doing. As our technological progress grows, it becomes increasingly difficult to keep a broad perspective of what is going on, and the tendency to specialization grows stronger.

The day of the plant superintendent who was able to boast that he could perform every one of the jobs in his shop with equal skill is rapidly vanishing. The business executive who could describe every intricate detail of his enterprise is becoming rare. And the family doctor once thought suitably equipped to handle almost any kind of ailment finds increasing need for consultation with specialists.

With each passing year there is an ever-higher rate of skilled personnel crawling into hard shells of specialization that prevent over-all contact with their industrial and professional neighbors. Worse yet, these persons become divorced from all community activity. Yet the need is great for a better understanding among business, industry, and the professions. In turn these segments of our economy owe much to the communities in which they prosper, and persons owe to each other the obligation to be good neighbors.

It is my sincere belief that local medical societies should encourage each individual member to participate in some civic undertaking. We physicians should be rendering health leadership in all service

clubs, chambers of commerce, fraternal and veterans organizations, PTA groups, church associations, and unions. We cannot expect these organizations to be interested in our problems if we are not interested in theirs. Doctors should rub elbows on a social and organizational basis with persons outside the profession. There is much good to be gained in taking the time to learn the troubles of the other fellow. A diet limited to one-track ideas can lead only to social anemia.

If we are to continue serving the public effectively, we must seek out the facts on what the public wants. Getting together with representatives of groups

outside the medical profession is one way of gaining these facts. And while we are doing this job of research we will be better able to impart to the laity the facts of our own service in the public interest.

The more than 140,000 members of the A.M.A. have no reason to be apologists for their profession. They need only to take advantage of the opportunity to tell the story of our positive program in 140,000 different ways. If any individual physician feels he does not have enough facts at his command, I highly recommend the reading of President-Elect Walter B. Martin's superb statement presented before the House Committee on Interstate and Foreign Commerce. This statement was published in *THE JOURNAL*, February 13, on page 589 of the Organization Section.

Here for the investment of a few minutes' reading time you will find the best, and one of the most complete, accounts of the American Medical Association's positive program for public service. It is the finest ammunition obtainable for the job that all of us must do collectively and as individuals.

EDWARD J. MCCORMICK, M.D., Toledo, Ohio

ORGANIZATION SECTION

MEDICAL ASSOCIATION OF THE ISTHMIAN CANAL ZONE

The Medical Association of the Isthmian Canal Zone, now in its 48th year, was established shortly after Gen. William C. Gorgas, M.C., U. S. Army, served as chief sanitary officer for the Panama Canal during the construction period, 1904-1914. According to the *Panama Canal Review*, when tropical medicine was in its infancy the association served as a clearing house where members could discuss mutual problems and give one another sometimes a much-needed boost along paths that were just being explored. Two of the charter members remain on the Isthmus: Dr. Harry Eno, who, after 10 years at Ancon Hospital, retired to private practice in Colon, Republic of Panama, where for several years he was head of the Samaritan Hospital, and Dr. Dennis F. Reeder, president of the association in 1914, who resigned as chief of Ancon's eye, ear, nose, and throat clinic in 1916 to help establish the Hospital de Panama in Panama City, where he is still in active practice. Another of the first members, the late Dr. Samuel T. Darling, in 1906 shortly after the formation of

the association, gave to the world the first description of histoplasmosis and in 1909 described trypanosomiasis of domestic stock, first recognized on the Isthmus by him. Dr. Darling, who for six years was the first chief of the Board of Health Laboratory in Ancon, was president of the American Society of Tropical Medicine in 1924 and president of the Isthmian medical association in 1908. General Gorgas, whose coming to Panama gave strong impetus to medical science there, also served in these dual capacities, and in 1910 during his presidency of the American Medical Association, the Isthmian medical association was admitted as a constituent member. The first president of the Isthmian association was the late Dr. Alfred B. Herrick, who was head of the board of health laboratory from 1904 to 1906. Resigning as chief of the surgical clinic at Ancon Hospital in 1915, he helped establish the Hospital de Panama and the Herrick Clinic.

Other illustrious alumni include Dr. Herbert C. Clark, director of the Gorgas Memorial Laboratory in Panama City since its establishment in 1929; Dr. James Simmons, now dean of the Harvard School of Public Health in Boston; Dr. Lewis B. Bates, bacteriologist and serologist on the first permanent staff of the board of health laboratory and chief of the laboratory from 1919 to 1948, now living in Weymouth, Mass.; Dr. George R. Callender (Brig. Gen., retired, Washington, D. C.) first president of the Army Medical Research Board on the Isthmus; the late Dr. William E. Deeks, chief, medical clinic at Ancon Hospital, 1907-1910, and a medical director for the United Fruit Company; Dr. Edward I. Salisbury, New York, present head of the medical department of that company; Dr. Carl M. Johnson, health officer in Panama

City, former assistant director and protozoologist at Gorgas Memorial Laboratory; and Dr. William M. James, who collaborated with Dr. Deeks in research on malaria, blackwater fever, amebic dysentery, and associated chronic infections, and during whose administration the word "Isthmian" was added to the name of the association to distinguish it from the Suez and other canal zones. Brig. Gen. Elbert De Coursey, head of the Armed Forces Institute of Pathology, Washington, D. C., served the association as secretary in 1933 and as president in 1934, when he was pathologist at the Board of Health Laboratory.

Formed originally of physicians employed by the Isthmian Canal Commission, the association for many years enjoyed a semiofficial status, canal funds being used for publication of the proceedings of the association. In 1916 members of the Army Medical Corps stationed on the Isthmus were invited to join the association, and among them was Dr. George F. Lull, now Secretary and General Manager of the American Medical Association. Dr. Lull's son, now chief of the x-ray service at Gorgas Hospital, is one of the three "second generation" members of the association, the others being Dr. Feruccio Bertoli Jr., pathologist at Gorgas Hospital, and Dr. Lawrence M. Drennan Jr., assistant superintendent of the hospital.

The association holds most of its meetings at the Gorgas Memorial Laboratory. The officers are Dr. Irving J. Strumpf, Balboa, C. Z., president, and Dr. I. Robert Berger, Ancon, C. Z., secretary. The Isthmian association is this month participating in commemoration of the 50th year of Panamanian independence and the 50th year of the advent of American medicine in the Canal Zone by sponsoring the Inter-American Medical Convention in Panama City, March 24-26 (*THE JOURNAL*, Feb. 20, page 689). The association numbers among its members three former presidents of the Republic of Panama: Drs. Arnulfo Arias, Augusto S. Boyd, and Daniel Chaus Jr., and a former ambassador to the United States, Joaquin J. Vallarino, all of Panama City.

FEDERAL MEDICAL LEGISLATION

Medical Facilities, Surveys, and Construction

Senator Smith (R., N. J.) in S. 2758 proposes "to amend the hospital survey and construction provisions of the Public Health Service Act to provide assistance to the States for surveying the need for diagnostic or treatment centers, for hospitals for the chronically ill and impaired, for rehabilitation facilities, and for nursing homes, and to provide assistance in the construction of such facilities through grants to public and nonprofit agencies." This is an administration bill identical with H. R. 7341 (Wolverton) previously reported. The bill was referred to the Committee on Labor and Public Welfare.

Vocational Rehabilitation

Senator Smith (R., N. J.) in S. 2759 would "amend the Vocational Rehabilitation Act so as to promote and assist in the extension and improvement of vocational rehabilitation services, provide for a more effective use of available federal funds, and otherwise improve the provisions of that act." This is an administration bill based on the President's health message to Congress. The proposed bill would authorize appropriations to assist in the rehabilitation of handicapped persons in three ways: (1) grants to states to meet the cost of rehabilitation services, (2) six-year grants to states to extend and improve rehabilitation services, and (3) grants to states and to public and other nonprofit organizations and agencies to meet the cost of unique projects directed toward

The summary of federal legislation was prepared by the Washington Office of the American Medical Association and the summary of state legislation by the Bureau of Legal Medicine and Legislation.

the solution of regional or national rehabilitation problems. During the fiscal years 1955 and 1956 special project grants would be available for helping the states to plan and initiate a substantial expansion of their vocational rehabilitation programs.

Each state would have a minimum general grant of \$50,000, with a federal share varying from $\frac{1}{2}\%$ to $\frac{3}{4}\%$. The extension of improvement grants would carry a minimum allotment of \$5,000 for states, with the federal share varying from up to 75% of the costs for the first two years, 50% for the next two years, and 25% for the last two years. The states would be required to designate a single administrative agency and provide for personnel and administration standards to be approved by the Secretary of Health, Education, and Welfare. The state agency must agree to cooperate with the Bureau of Old Age and Survivors Insurance, the state agency administering the state public assistance program, and other bureaus providing vocational rehabilitation services. It is not intended in this bill to provide grants for major new construction. This bill was referred to the Committee on Labor and Public Welfare.

Grants to States

Senator Smith (R., N. J.) in S. 2778 has introduced the administration bill to make more uniform, yet flexible, distribution of funds in grants-in-aid for public health services. The bill would replace the present separate and extremely variable authorizations for grants to control individual disease with the authorizations for the following three types of grants: (1) grants to assist the states generally in meeting the costs of their public health service, (2) six-year grants to assist states in "initiating projects for the extension and improvement of their public health services," and (3) "grants to states and to public and other nonprofit organizations and agencies to assist in combating unusually severe public health problems in specific geographical areas, in the carrying out of special projects which hold unique promise of making a substantial contribution to the solution of public health problems common to a number of states, and in meeting problems of special national significance or concern." In the type 1 grant the financial formula would be based on the states relative population and fiscal resources as measured by the states per capita income, the same formula as is used in the Hill-Burton hospital act. Each state would have a minimum allotment of \$50,000 with the federal share from $\frac{1}{3}\%$ to $\frac{3}{4}\%$. In the type 2 grants, there would be a minimum state allotment of \$25,000 with the federal share up to 75% in the first two years, 50% in the next two years, and 25% for the last two years. The type 3 grant would be made by the Surgeon General from funds available for any one fiscal year. In allowing for the change-over for the new allotment formula, there would be a limit of 10% for any decrease of allotments which a state would receive in any one year. This bill was referred to the Committee on Labor and Public Welfare. Congressman Wolverton has introduced an identical bill, H. R. 7397, which was referred to the House Interstate and Foreign Commerce Committee.

Children's Service Act

Congressman Reed (R., N. Y.) proposes in H. R. 7448 to amend title 5 of the social security act to carry out the administration's recommendations of making federal grants more uniform. The bill would replace the bill separate authorizations for grants for maternal and child health, crippled children, and welfare agencies, with three types of grants: 1. General assistance to states to finance their child health and welfare services. The formula for determining each state allotment would consider the relative child population of the states and the per capita income. Each state would have the minimum of \$200,000 with the state share from $\frac{1}{3}\%$ to $\frac{3}{4}\%$. 2. Six-year grants to aid states in extending and improving child health and welfare service. There would be a minimum of \$5,000 for states with the federal share up to 75% for the first two years, 50% for the next two years, and 25% for the last two years. Of each state's allotment in type 1 and 2 grants, 19% would be for child welfare, 29% for crippled children, and 32% for maternal and child wel-

fare service. The remaining 20% would be allotted among these services by the state governor. 3. Grants to states and public and nonprofit institutions of higher education to meet the costs of projects to solve child health and welfare problems of national significance. To be eligible for federal allotment, a state would have to submit plans to the Secretary of Health, Education, and Welfare and to the Child Assistance and Welfare programs. The bill authorized 41 million dollars to be appropriated annually, the same as of present, but the administration estimates that only 30 million dollars will be needed, the same as is currently provided.

STATE MEDICAL LEGISLATION

Arizona

Bills Introduced.—H. 182, proposes certain amendments to the law relating to the licensing and vaccination of dogs for the purpose of controlling rabies. H. 206, to amend the law relating to the sale of certain drugs without a prescription, proposes to add to the list of drugs "antibiotics, including but not limited to penicillin, streptomycin, aureomycin, chloramphenicol and bacitracin." H. 219, proposes that no medical preparation or appliance having special utility for the prevention of venereal disease shall be sold except by an establishment holding a state license issued by the state board of pharmacy, nor shall any such preparation or appliance be advertised except in a professional publication the circulation of which is limited primarily to the drug trade or physicians. The prohibitions of the act would not apply to a duly licensed physician in the regular course of his practice.

Kentucky

Bills Introduced.—H. 178, proposes an appropriation for the purpose of making loans and scholarships for the study of medicine by students who are bona fide residents of Kentucky and who desire to become physicians and are acceptable for enrollment in a medical school approved by the state board of health. S. 104, proposes the creation of a Kentucky board of ophthalmic dispensers to examine, license, and regulate ophthalmic dispensers.

Maryland

Bills Introduced.—H. 27, proposes to amend the definition of the practice of chiropody to mean the diagnosis, surgical, medical, or mechanical treatment of all ailments of the human foot. The term "surgical" is defined for the purposes of this subtitle as limited to the soft tissues of the foot, superficial to the deep fascia and to the toes; with the amputation of a toe or toes and the use of an anesthetic, other than local, prohibited.

Massachusetts

Bills Introduced.—H. 1939, proposes that a person shall not perform on a living mammalian animal any pain-producing experiment except subject to the restrictions of the proposal and it makes it an offense for any person to perform or take part in the performing of any experiment in contravention to the proposal's provision. Licenses to persons authorized to engage in such experiments would be issued by the commissioner of public safety. H. 2351, proposes the creation of a special commission to make an investigation and study relative to the training of medical laboratory technologists. S. 508, proposes that the department of mental health shall not employ any European psychiatric doctor who is of foreign birth and education, relative to certain patients in the department of mental health.

Mississippi

Bills Introduced.—H. 208, proposes to require the examination of applicants for drivers' licenses so as to test the applicant's eyesight and also authorizes such further physical and mental examination as the commissioner of public safety finds necessary to determine the applicant's fitness to operate a motor vehicle safely upon the highways. H. 398, proposes to empower the board of trustees of state institutions of higher learning to prescribe standards for schools of nursing and to administer scholarship funds for nursing students. H. 426, proposes the establishment of a program for study in nursing, together with the establishment of 1,000 scholarships in nursing education. H. 427, proposes to amend the nursing practice act by including provisions relating to the licensing of practical nurses. S. 1293, proposes the creation of a state examining committee for physical therapists and defines physical therapy as the treatment of disease or injury of any person by the use of physical, chemical, and other properties of heat, light, water, electricity, massage, and therapeutic exercise, including posture and rehabilitation procedures. The use of roentgen rays and radium for diagnostic purposes, including cauterization, are not authorized. S. 1356, proposes to amend the Mississippi law so as to exempt from jury service nurses, nurses aids, and hospital attendants actually engaged in their vocation. S. 1320, proposes the enactment of a system for vaccinating dogs for rabies so as to control the spread of rabies throughout the state. S. 1341, proposes the creation of a scholarship program for nursing education. S. 1342, proposes to authorize the Board of Trustees of State Institutions of Higher Learning to prescribe standards for Schools of Nursing and to administer scholarship funds for nursing students. S. 1405, proposes the creation of a board of chiropractic examiners and defines chiropractic as the science, art, and philosophy of things natural; a system of locating and adjusting the subluxations of the articulations of the human spine and its adjacent tissues for the correction of the cause of disease.

MEDICAL NEWS

CALIFORNIA

Surgical Forum in Los Angeles.—The Society of Graduate Surgeons of the Los Angeles County Hospital will hold its annual surgical forum March 1-5 at the Ambassador Hotel, Los Angeles. Guest lecturers will be Drs. Robert S. Dinsmore, Cleveland, I. Mims Gage, New Orleans, Francis D. Moore, Boston, Hans Selye, Montreal, Canada, and Robert M. Zolinger, Columbus, Ohio. The forum will consist of daily presentations by each of the guest lecturers. At the end of each day the entire faculty will be available for discussions. The registration fee, \$85, includes the cost of the four luncheons and the banquet at the conclusion of the week's activities. Application, accompanied by a check for the registration fee, should be mailed to Dr. Eugene J. Joergenson, Chairman, Registration Committee, 540 N. Central Ave., Glendale 3. Attendance is limited to 250 persons.

CONNECTICUT

Lecture on Diabetes.—Dr. Theodore Lidz, professor of psychiatry, Yale University School of Medicine, New Haven, will present "Psychotherapeutic Aspects of Diabetes Mellitus" at the Hartford Hospital, Feb. 27, 11 a. m.

Teaching Program in Rehabilitation.—The Yale University School of Medicine, New Haven, has received from the National Foundation for Infantile Paralysis a five year "March of Dimes" grant of \$150,000 for a teaching program in rehabilitation for poliomyelitis patients as well as other disabled persons. Dr. Thomas F. Hines, assistant professor of medicine and director of physical medicine and rehabilitation, will administer the program, intended primarily to stimulate the teaching of basic concepts and techniques of total rehabilitation to medical students. The funds will be used for increasing the staff of the present rehabilitation service operated at the Grace-New Haven Community Hospital, as well as the scope of its program, and for continued clinical research in the field of rehabilitation.

DISTRICT OF COLUMBIA

Custis Hall Memorial Lecture.—The Washington Orthopedic Club will present the Custis Lee Hall memorial lecture at 8:30 p. m. March 1 in the auditorium of the Medical Society of the District of Columbia, Washington, D. C. Dr. Leo Mayer, New York, will discuss "The Evolution of Tendon Surgery."

Posthumous Award to Colonel Halloran.—A bronze plaque in honor of the late Col. Roy D. Halloran, M.C., was recently unveiled at the Walter Reed Army Medical Center, Washington, D. C., and the Army's Certificate of Achievement was awarded to him posthumously. The plaque, donated by the American Psychiatric Association, was presented by Dr. Winfred Overholser, superintendent of Saint Elizabeths Hospital, Washington, D. C., to Major Gen. Leonard D. Heaton, M.C., Commanding General of the Center, and the certificate by Major Gen. George E. Armstrong, Army Surgeon General, to Colonel Halloran's son and daughter. The certificate credits Colonel Halloran for establishing the groundwork for the Army's present-day psychiatric program in World War II.

FLORIDA

Lecture on Cardiac Surgery.—Dr. George H. Humphreys, New York, will give an illustrated talk on cardiac surgery at 8:30 p. m. March 1 at Memorial Hall, Jackson Memorial Hospital, Miami, under the sponsorship of the Greater Miami chapter, American College of Surgeons.

Physicians are invited to send to this department items of news of general interest, for example, those relating to society activities, new hospitals, education and public health. Programs should be received at least three weeks before the date of meeting.

GEORGIA

Eye Bank in Atlanta.—The Ponce de Leon Eye, Ear, Nose and Throat Infirmary, Atlanta, affiliated with the national Eye Bank for Sight Restoration, Inc., is offering its services for those who wish to donate their eyes to the eye bank at time of death. Physicians may obtain the necessary forms from the infirmary, which will make all arrangements after notification by the physician.

Health Forums.—The Fulton County Medical Society is sponsoring a series of public health forums at the Tower Theater, Atlanta. The following programs will be presented in March by Atlanta physicians: March 2 "You and Your High Blood Pressure" (moderator, Dr. Bernard L. Shackleford; speaker, Dr. Arthur J. Merrill); March 9 "You and Your Nervous Tension" (moderator, Dr. William G. Hamm; speaker, Dr. Paul L. Schroeder); March 16 "You and Your Diabetes" (moderator, Dr. Eugene B. Ferris; speaker, Dr. Christopher J. D. McLoughlin); March 23 "You and Your Stomach Ulcers" (moderator, Dr. Eustace A. Allen; speaker, Dr. E. Napier Burson Jr.).

ILLINOIS

Psychiatric Lectures.—In its series on treatment in psychiatry, which is open without charge to all physicians, the North Shore Health Resort, 225 Sheridan Road, Winnetka, offers a lecture "The Role of the Family in Emotional Disorders" by Jules Henry, Ph.D., associate professor of anthropology, Washington University, St. Louis, on March 3, 8 p. m.

Rehabilitation Services.—The Illinois division of vocational rehabilitation, a state-federal service, announces that in 1953 it rehabilitated into remunerative services 3,812 handicapped persons. The division provides for the handicapped an opportunity for job preparation equal to that which the public education program provides for the nonhandicapped. The following services are available to vocationally disabled persons regardless of ability to pay: (1) complete diagnostic service—medical examinations, specialist and clinical study, psychiatric study, and psychological testing; (2) guidance based on diagnosis and case study; (3) training tuition; and (4) placement and follow-up. For those not financially able to obtain them, the following services are available: (1) medical, surgical, hospital, and psychiatric service, and occupational and physical therapy, if diagnosis indicates cure or substantial improvement in a reasonable length of time; (2) artificial appliances; (3) training supplies; (4) maintenance and travel during training (not public assistance; covers only increased expense resulting from the rehabilitation plan); and (5) occupational tools and equipment for use in a trade or business.

The services of the division are available only in cases of substantial vocational handicap in which there is reasonable expectancy that the service will result in employment. Acute temporary disabilities, such as appendicitis or pneumonia, cannot be treated, nor can chronic disabilities, such as tuberculosis. Vocational services are rendered only after the chronic ailment has been diagnosed as slowly progressive, arrested, or likely to be arrested in a reasonable time and with no more than 90 days of hospitalization. The division points out that the physician's office is the best source of referral to the division and that through his cooperation many more needy handicapped people can be rehabilitated.

Chicago

Hektoen Commemorative Services.—The second Ludwig Hektoen commemorative services, sponsored by the Chicago Pathological Society, will be held March 14 at 11 a. m. in the Hyde Park Baptist Church, 5600 Woodlawn Ave., where portions of Mozart's Requiem will be sung by the choir, assisted by members of the Chicago Symphony Orchestra. All are invited to attend.

Annual Medical Society Clinical Conference.—The Chicago Medical Society will present the annual clinical conference March 2-5 at the Palmer House, Chicago. Daily round-table luncheons will be preceded and followed on Tuesday, Wednesday, and Thursday by color television from Cook County Hospital. Out-of-state speakers include:

Tom D. Spies, Birmingham, Ala., Vitamins as Therapeutic Agents.
 Ferdinand C. Helwig, Kansas City, Mo., Diagnosis and Management of Breast Tumors.
 James H. Maxwell, Ann Arbor, Mich., Diseases of the Parotid Glands.
 Stewart G. Wolf, Oklahoma City, Role of Stress in Peptic Ulcer.
 Marion B. Sulzberger, New York, Dermatological Disorders Commonly Encountered in General Practice.
 Robert A. Ross, Chapel Hill, N. C., Importance of Conservatism in Gynecology.
 Henry K. Beecher, Boston, Early Care of the Severely Injured.
 Paul W. Schafer, Kansas City, Kan., Management of Asymptomatic Solitary Circumscribed Pulmonary Opacities.
 Harry L. Alexander, St. Louis, Allergic Reactions to Drugs.
 Robert Elman, St. Louis, Management of Intestinal Obstruction.
 Bernard Becker, St. Louis, Retinal Complications of Diabetes Mellitus.
 Charles C. Higgins, Cleveland, Significance of Hematuria.
 Francis D. Murphy, Milwaukee, Types of Hypertension.
 Louis Leiter, New York, Medical Treatment of Hypertension.
 Reginald H. Smithwick, Boston, Surgical Treatment of Hypertension.
 Herman H. W. Kumm, New York, Present Status of Prophylaxis in Poliomyelitis.
 Alan F. Guttmacher, New York, Treatment of Hemorrhage in Obstetrics and Gynecology.
 Stewart H. Clifford, Boston, Infection in the Newborn.
 J. Murray Kinsman, Louisville, Ky., Medical Infections of the Kidney.

The Tuesday sessions will end with a clinicopathological conference, 4:30-5:30 p. m.; the Thursday sessions with a panel discussion on blood diseases, 4-5 p. m.; and the Friday meeting with a panel on obstetrics and gynecology, 3:30-4:30 p. m. The registration fee is \$5.

MAINE

Medical Legal Conference.—The semiannual meeting of the Maine Medico-Legal Society, Feb. 4-5 in Portland, was dedicated to Dr. George L. Pratt, Farmington, the "father of the society," who has served as secretary since its formation in 1935. The conference on medical legal techniques in the investigation and prosecution in cases of violent and suspicious deaths included round tables on law enforcement and the crime problem, concepts of limited responsibility, medical legal advancement since the turn of the century, use of circumstantial evidence, the trial of a crime detection case, and problems of the medical examiner. The evening meeting was addressed by the Hon. Eugene Cook, Atlanta, president of the Attorneys General Association of the United States, and attorney general for Georgia, whose topic was "A New Look at State and Federal Crime Problems."

MICHIGAN

Hickey Memorial Lecture.—Wayne University College of Medicine, Wayne County Medical Society, and the Detroit Roentgen Ray and Radium Society announce the Hickey memorial clinic and lecture and a testimonial dinner for Dr. Lawrence Reynolds, professor of roentgenology at the college of medicine, March 4. In the morning Drs. H. Dabney Kerr, Iowa City, and Harold W. Jacox, New York, will speak on carcinoma of the cervix, and in the afternoon Drs. Eugene P. Pendergrass, Philadelphia, and Wendell G. Scott, St. Louis, will discuss "Vascular Radiography." The Hickey memorial lecture by Dr. Reynolds at 4 p. m. will be followed by a testimonial dinner at the Veterans Memorial Building, to which Dr. Reynolds' friends and associates are invited. Dr. Reynolds will be honored by the establishment of a Lawrence Reynolds Radiological Niche in the new Wayne University Library.

MONTANA

State Association Interim Session at Helena.—The Montana Medical Association will hold its interim session March 5-6 in the Placer Hotel, Helena, under the presidency of Dr. Sidney C. Pratt, Miles City. Dr. Raymond F. Peterson, Butte, will serve as moderator for a clinicopathological conference Friday, 1:45 p. m., with the following participants: Drs. John

H. Bridenbaugh and Wayne Gordon, Billings; Dr. Alfred M. Lueck, Livingston; and Dr. John C. Wolgamot, Great Falls. At 4:10 p. m., through the courtesy of the Montana chapter of the National Foundation for Infantile Paralysis, Inc., Dr. Carl J. Potthoff, Rochester, Minn., will discuss "Recent Developments Toward a Vaccine Against Poliomyelitis." Dr. Pratt will serve as toastmaster for the banquet, 7:30 p. m., at which the Rev. Dr. Paul B. McCleave, pastor of the First Presbyterian Church, Bozeman, and former president of the College of Emporia, Kansas, will present "John Q. Looks at the Doctor."

NEW YORK

Society News.—At the meeting of the Rochester Academy of Medicine (1441 East Avenue) March 2, 8:30 p. m., Dr. James B. Amberson, New York, will speak on tuberculosis. The April 6 meeting will be addressed by Dr. Willard M. Allen, St. Louis, who will discuss "The Adrenogenital Syndrome."

Course on Arthritis.—The University of Buffalo School of Medicine offers a postgraduate course on arthritis March 3 at the Buffalo General Hospital. The program will open with "Action of Antirheumatic Drugs" by Dr. Bernard M. Norcross, after which case presentations will be made on gout, rheumatoid arthritis, rheumatoid spondylitis, osteoarthritis, and collagen disease. An arthritis clinic, 2-4 p. m., will be followed by demonstration of the use of physical therapy in arthritis. The fee for the course is \$15. Request for registration should be sent to Dr. Milton Terris, Assistant Dean for Postgraduate Education, University of Buffalo School of Medicine, 3435 Main St., Buffalo 14.

Personal.—Dr. Walter T. Hausheer, Staten Island, has joined the medical department of the Standard Oil Development Company. Dr. Hausheer served for more than four years with the Navy during World War II.—Dr. Duncan W. Clark, professor of environmental medicine and community health at the State University of New York College of Medicine at New York City, Brooklyn, was elected chairman of the Conference of Professors of Preventive Medicine at a meeting, Nov. 9, 1953, held during the annual convention of the American Public Health Association at the Hotel Statler.—Dr. Wesley T. Pommerenke, associate professor of obstetrics and gynecology, University of Rochester School of Medicine and Dentistry, left Rochester Dec. 18, 1953, for an eight-month lecture-teaching tour in Syria, India, and Japan. He will lecture at the American University of Beirut, Lebanon, then spend three months as visiting professor of obstetrics and gynecology at the University of Madras, India, under the sponsorship of the Unitarian Service Committee, a nonsectarian voluntary organization, and another three months as visiting professor at Keio Gijuku University, Tokyo, Japan. At the request of the Indian minister of health, Dr. Pommerenke will stop at New Delhi for conferences on his teaching program. A year ago Dr. Pommerenke was an American delegate to the World Conference on Population Problems in Bombay and last April addressed the Mexican Society for the Study of Sterility.—Dr. Emanuel Schwartz, Brooklyn, has been appointed to the three-member medical practice committee of the New York State Workmen's Compensation Board, succeeding Dr. Joseph Raphael, also of Brooklyn, who retired Dec. 31, after serving as a member of the committee since 1944. The other members of the committee are Dr. Francis M. Conway, New York, chairman, and Dr. Chester L. Davidson, Jamaica.

New York City

Hospital News.—Dr. Edward E. Fischel, who has been engaged in teaching and research at the Presbyterian medical center, has been appointed full-time director of medicine at the Bronx Hospital and will assume his duties on May 1.—On March 5 Dr. Albert Tannenbaum, director, department of cancer research, Medical Research Institute, Michael Reese Hospital, Chicago, will present "Some Aspects of Nutrition in Cancer" at 3 p. m. in the social hall of Montefiore Hospital for Chronic Diseases.

Symposium on Cancer.—The New York Cancer Society will present the following symposium on recent experiences in the higher energy irradiations in cancer therapy March 2, 8:30 p. m., at the New York Academy of Medicine, Fifth Ave. at 103rd St.:

Supervoltage Radiation in Treatment of Cancer, Hugh F. Hare, Los Angeles.

Preliminary Observations with 22 MEV Radiation in Treatment of Cancer, James J. Nickson, New York.

Experiences with the Cobalt 60 Beam Teletherapy Unit in Treatment of Cancer, Jacob R. Freid, New York.

Physicians and medical students are invited.

Program on Radioisotopes.—"The Practical Clinical Application of Radioisotopes in Medical Diagnosis and Treatment" will be presented in the Main Lecture Hall, New York University College of Medicine, 477 First Ave. (near 28th St.), March 1, 8:30 p. m. Dr. Maxwell H. Poppel, professor and chairman, department of radiology, New York University College of Medicine, will preside over the following program:

Use of Radioisotopes in the Study of Blood Volume, Solomon A. Berson.

Radioactive Iodine in Diagnosis of Thyroid Disorders, Solomon Silver. Radioactive Phosphorus in Leukemia, Polycythemia Vera, and Superficial Skin Lesions, and Colloidal Radioactive Phosphorus for Interstitial Use in Cancer, Bernard Roswit.

Use of Radioactive Gold in Malignant Peritoneal and Pleural Effusions, Sidney Rubinfeld.

OHIO

Society News.—The Academy of Medicine of Cincinnati will have as guest speaker March 2 Dr. Charles K. Friedberg, assistant clinical professor of medicine, Columbia University College of Physicians and Surgeons, New York, who will discuss "Drugs in the Treatment of Heart Disease." March 16 Dr. Carl V. Moore, professor of medicine, who will become dean of Washington University School of Medicine, St. Louis, March 15, will present the Roger Morris lecture, "New Concepts About Thrombocytopenic Purpura, Sensitivity to Platelets, and Platelet Types."

Dr. Vilter to Make Egyptian Survey.—Dr. Richard W. Vilter, associate professor of medicine, University of Cincinnati College of Medicine, and a member of the committee on dietary allowances of the National Research Council, has been selected by the World Health Organization to survey for the United Nations the causes of anemia and nutritional deficiency diseases in Egypt. During his two month study he is to determine what substance may be lacking in the native diet and recommend to the Egyptian government what can be done to replace the missing substance. Egyptians depend largely on a corn-meal diet.

PENNSYLVANIA

Society News.—The Philadelphia County Medical Society announces that, effective March 1, Mr. Laurence S. Whyte will become its business manager. Miss Dorothy Ann Harrison, former executive assistant, has been appointed editor of *Philadelphia Medicine*. The offices of the publication are in the society building, 301 S. 21st St., Philadelphia.

Secretaries-Editors Conference.—The 42nd annual conference of secretaries and editors of the component county medical societies of the Medical Society of the State of Pennsylvania will be held in Harrisburg, March 4-5. Discussions on the activities of the state medical society and the duties of county society officers will be held Thursday afternoon. Wilton M. Krogman, Ph.D., professor of anthropology at the Graduate School of Medicine, University of Pennsylvania, speaker at the dinner, Thursday, 6 p. m., will have as his subject "Dry Bones!" On Friday morning the problem of caring for non-service-connected disabilities of veterans will be discussed, as will "The D. P. A. Experimental Payment Program," "Polio Vaccine in Pennsylvania," "The Rural Medical Service Survey," and "The Ethical Relationship of the Physician to Media of Public Information."

Philadelphia

Anders Lecture by Howard Rusk.—On March 3, 8:30 p. m., the College of Physicians of Philadelphia will present the James M. Anders lecture. Dr. Howard A. Rusk, professor and chairman, department of physical medicine and rehabilitation, New York University College of Medicine, will discuss "The Physician and the Changing World."

VIRGINIA

Personal.—Dr. James N. Dudley, commissioner of health at Roanoke since September 1946, has resigned and has accepted a position with the Lovelace Clinic at Albuquerque, N. Mex. —Dr. A. McGarvey Wallace, Gate City, who recently was awarded his certificate for 50 years of practice of medicine by the Medical Society of Virginia, flew his own plane to Roanoke for the presentation.

Graduate Lecture Program.—The University of Virginia Department of Medicine, Charlottesville, invites all physicians to attend, without fee, its spring series of graduate lectures. The program for March includes:

March 1, William B. Castle, Boston, Some Immunologic Aspects of Disorders of the Blood.

March 8, Roy R. Grinker, Chicago, Some Newer Aspects of Psychosomatic Medicine.

March 15, Harry Eagle, Bethesda, Md., Studies of the Mode of Action of Penicillin.

March 22, George W. Wright, Cleveland, Measurement of Respiratory and Cardiac Circulatory Reserves.

March 29, Oliver H. Lowry, St. Louis (title to be announced).

GENERAL

Thirty-Eighth Medical Golfing Association Tournament.—The golfers of the American Medical Association will meet at the Olympia Country Club in San Francisco on June 21, to compete in the 38th tournament of the American Medical Golfing Association. In anticipation of a large registration, the California committee has completed many arrangements to make this an outstanding event. Dr. Edward Campion, San Rafael, California, is President of the American Medical Golfing Association. Information may be obtained also from W. H. Bartleson, Executive Secretary, Jackson County Medical Society, 3036 Gillham Road, Kansas City 8, Mo.

American College of Gastroenterology.—At a meeting of its executive committee Jan. 10 in New York, the National Gastroenterological Association became the American College of Gastroenterology, with Dr. Sigurd W. Johnsen, Passaic, N. J., president of the association, and all other officers and committees assuming the same offices in the college. Applicants for fellowship in the college must have at least five years' training in gastroenterology at institutions or medical colleges that meet the standards set up by the board of trustees of the college. A regional meeting of the college will be held in Milwaukee March 28 and the annual meeting in Washington, D. C., Oct. 25-30.

Fellowships in Ophthalmology.—The National Council to Combat Blindness announces the launching of its fellowship program, the objectives of which are: (1) to meet the existing shortage of trained research manpower in the field of ophthalmology and its related sciences and (2) to encourage persons who have training in ophthalmology or the various branches—biological, chemical, and physical sciences—and clinical investigative medicine to undertake specialized research study. Under the conditions of these fellowships the applicants are required to make their own arrangements for suitable research facilities with recognized institutions. Numerous grants-in-aid are also awarded. Applications for 1954-1955 fellowship and grant-in-aid awards of the National Council to Combat Blindness will be considered at the fifth annual meeting in the spring. Completed applications should be received in the office of the council no later than April 15. Application forms may be obtained from the Secretary, National Council to Combat Blindness, 30 W. 59th St., New York 19.

Symposium on Gerontology.—Johns Hopkins University School of Hygiene and Public Health, Baltimore, and the National Vitamin Foundation will present a symposium on problems of gerontology, March 2, at the Biltmore Hotel, Madison Ave. at 43rd St., New York. The following presentations will be made:

- Nathan W. Shock, Ph.D., Baltimore, Physiological and Biochemical Studies of Aging.
 Albert I. Lansing, Ph.D., St. Louis, Role of Comparative Physiology in the Study of Aging.
 Harry J. Deuel Jr., Ph.D., Los Angeles, Fat Metabolism.
 Charles S. Davidson, Boston, Protein Metabolism.
 Bacon F. Chow, Ph.D., Baltimore, Absorption of Vitamins and Enzymic Activities in Aging.
 John Esben Kirk, St. Louis, Blood and Urine Vitamin Levels in the Aged.
 Frank H. Bethell, Ann Arbor, Mich., Hemopoietic Factors.
 C. N. Long, New Haven, Conn., The Hormones and Metabolism.
 Dwight J. Ingle, Ph.D., Chicago, Endocrine Stress and Aging.
 Henry A. Rafsky, New York, Nutritional Problems of the Aged.

There is no registration charge. Information may be obtained from the National Vitamin Foundation, 15 E. 58th St., New York 22.

Sectional Surgeons Meeting in Omaha.—The American College of Surgeons will hold a sectional meeting at the Hotel Fontenelle in Omaha, March 1-4. The general surgery sessions will include panel discussions on uterine malignancy, jaundice, intestinal obstruction, and pediatric surgery. Symposia will be featured on trauma, preoperative and postoperative care; vascular surgery, and congenital defects in children. The meetings in obstetrics and gynecology will have a panel discussion on bleeding during the first trimester of pregnancy and a symposium on management of prolonged labor. A symposium on management of lesions of the esophagogastric junction will be presented at the session on thoracic surgery, and the urologic sessions will hear panel discussions on surgery of hydronephrosis, of the adrenal, ureters in radical pelvic surgery, and undescended testis. Dr. Evarts A. Graham, St. Louis, is scheduled to present "More Evidence About the Relationship of Cigarettes to Cancer of the Lung" Tuesday morning. Dr. Earl A. Connolly, Omaha, chairman of the committee on arrangements, will preside over the dinner meeting Tuesday, at which Dr. Paul R. Hawley, director of the American College of Surgeons, will discuss "The Responsibilities of Medical Citizenship." A cancer symposium will follow, with Dr. H. Mason Morfit, Denver, as moderator.

Delay in Poliomyelitis Validity Tests.—The president of the National Foundation of Infantile Paralysis, Mr. Basil O'Connor, has announced that, because of delays in the manufacture of the trial poliomyelitis vaccine, the nationwide validity tests are expected to get under way in late March or early April. It had been hoped that the injection of school children taking part in the tests could begin in February. Mr. O'Connor said: "While production problems have postponed the date for the start of the trials, we plan to inoculate a sufficient number of children before June to determine scientifically the value of this product." He explained that most of the virus is grown at the Connaught Medical Research Laboratories, University of Toronto. The virus is then shipped to pharmaceutical and biological concerns for conversion into vaccine, which requires several weeks. Each lot of the vaccine is subjected to safety tests by three independent laboratories. The vaccine to be tested, developed under a March of Dimes grant by Dr. Jonas E. Salk of the University of Pittsburgh, is currently being produced on a nonprofit basis. Dr. Salk is extending his studies to at least 5,000 persons in Allegheny County, Pa., before the start of the national foundation field trials. A small amount of the commercially produced vaccine was expected to be available for Dr. Salk's studies in February, but the large quantities needed for the field trials cannot be processed, tested, and packaged for shipment before the last week in March. The vaccine trials are being organized with the advice of the national foundation's scientific committees and that of special committees appointed by the Association of State and Territorial Health Officers, with Dr. Hart E. Van Riper, New York, national foundation medical director, in charge of the project. The test areas are being selected on recommendation of individual state health officers, based on scientific criteria.

LATIN AMERICA

Clinicopathological Conferences.—Shortly after the International Cancer Congress (July 23-29) in São Paulo, Brazil, a Brazilian Clinical-Pathologic Debates Week will be observed in Curitiba, Paraná, Brazil, Aug. 2-7. A seminar on morbid anatomy slides and a series of debates on clinicopathological subjects have been scheduled, and it is hoped that plans for a national society of pathology may be formulated during the sessions. Information may be obtained from Dr. Atys Quadros da Silva, Visc. Guarapuava 3200, Curitiba, Paraná, Brazil.

FOREIGN

Congress of Psychiatry in Italy.—The 25th Congress of the Italian Association of Psychiatry will convene in the Neuropsychiatric Hospital, Varese, May 6-9. Reports will be given on (1) recent discoveries in infantile encephalopathy, such as phenylpyruvic oligophrenia by Rh factor, maternal rubella, and thesaurismosis, and (2) new perspectives in quantitative differentiation between psychasthenia and schizophrenia. The participation of foreign colleagues is desired. The program of the conference will include excursions and cultural activities. The fee is 3,000 lire (\$4.80). Address correspondence to: Presidency of 25th National Congress of the Italian Psychiatric Society, Ospedale Neuro-Psichiatrico, Varese, Italy.

International Congress of Catholic Doctors.—Organized by the Irish Guild of St. Luke, SS. Cosmas and Damian (Veritas House, 7 Lower Abbey St., Dublin), the Sixth International Congress of Catholic Doctors will be held in Dublin, Ireland, from June 30 to July 4. Delegates from some 38 countries will consider the moral and medical aspects of world population trends in discussions on demographical, obstetric and pediatric, geriatric, psychological, social, and nutritional problems, and the influence of these problems on emigration. Inquiries may be addressed to Dr. Joseph J. Toland Jr., 4605 Leiper St., Philadelphia 24, president of the Federation of Catholic Physicians Guilds in the United States, or to the Right Rev. Monsignor Donald A. McGowan (National Catholic Welfare Conference, 1312 Massachusetts Ave., N. W., Washington, D. C.).

CORRECTION

HEW Department Budget.—Under this heading in the Washington News in THE JOURNAL, Feb. 6, advertising page 15, the second sentence should have read: "The total is about 200 million dollars less than the budget for the current fiscal year." The figure in the last sentence of that paragraph should have been 1.2 billion dollars.

MEETINGS

AMERICAN MEDICAL ASSOCIATION: Dr. George F. Lull, 535 North Dearborn St., Chicago 10, Secretary.

1954 Annual Meeting, San Francisco, June 21-25.

1954 Clinical Meeting, Miami, Florida, Nov. 30-Dec. 3.

1955 Annual Meeting, Atlantic City, N. J., June 6-10.

1955 Clinical Meeting, Boston, Nov. 29-Dec. 2.

1956 Annual Meeting, Chicago, June 11-15.

NATIONAL CONFERENCE ON RURAL HEALTH, Baker Hotel, Dallas, Texas, Mar. 4-6. Mrs. Arline Hibbard, 535 N. Dearborn St., Chicago 10, Secretary.

AERO MEDICAL ASSOCIATION, Hotel Statler, Washington, D. C., March 29-31. Dr. Thomas H. Sutherland, P. O. Box 26, Marion, Ohio, Secretary.

ALABAMA, MEDICAL ASSOCIATION OF THE STATE OF, Mobile, April 15-17. Dr. Douglas L. Cannon, 537 Dexter Ave., Montgomery, Secretary.

AMERICAN ACADEMY OF GENERAL PRACTICE, Cleveland, March 22-25. Mr. Mac F. Cahal, 406 West 34th St., Kansas City 2, Mo., Executive Secretary.

AMERICAN ASSOCIATION OF ANATOMISTS, Hotel Galvez, Galveston, Texas, April 7-9. Dr. Noimand L. Hoerr, 2109 Adelbert Road, Cleveland 6, Secretary.

AMERICAN ASSOCIATION OF IMMUNOLOGISTS, Ambassador Hotel, Atlantic City, N. J., April 11-15. Dr. John Y. Sugg, 1300 York Ave., New York, Secretary.

AMERICAN ASSOCIATION OF PATHOLOGISTS AND BACTERIOLOGISTS, Philadelphia, Pa., April 8-10. Dr. Alan R. Moritz, 2085 Adelbert Road, Cleveland 6, Secretary.

AMERICAN ASSOCIATION OF RAILWAY SURGEONS, Drake Hotel, Chicago, April 6-8. Dr. Chester C. Guy, 5800 Stony Island Ave., Chicago 37, Secretary.

AMERICAN COLLEGE OF ALLERGISTS, Roney Plaza Hotel, Miami Beach, Fla., April 5-10. Dr. Fred W. Wittich, 423 LaSalle Medical Bldg., Minneapolis 2, Secretary.

AMERICAN COLLEGE OF PHYSICIANS, Municipal Auditorium, Philadelphia, April 25-29. Mr. E. R. Loveland, 4200 Pine St., Philadelphia 4, Executive Secretary.

AMERICAN DERMATOLOGICAL ASSOCIATION, The Greenbrier, White Sulphur Springs, W. Va., April 13-17. Dr. J. Lamar Callaway, Duke Hospital, Durham, N. C., Secretary.

AMERICAN HEART ASSOCIATION, Conrad Hilton Hotel, Chicago, April 1-4. Dr. William H. Bunn, 44 East 23d St., New York 10, Secretary.

AMERICAN ORTHOPSYCHIATRIC ASSOCIATION, Hotel Commodore, New York, March 11-13. Dr. Marion F. Langer, Room 210, 303 Lexington Ave., New York 16, Executive Secretary.

AMERICAN PHYSIOLOGICAL SOCIETY, Ambassador Hotel, Atlantic City, N. J., April 10-16. Dr. Milton O. Lee, 2101 Constitution Ave., Washington 25, D. C., Executive Secretary.

AMERICAN PSYCHOSOMATIC SOCIETY, Jung Hotel, New Orleans, March 27-28. Dr. Theodore Lidz, 333 Cedar St., New Haven 11, Conn., Secretary.

AMERICAN RADIUM SOCIETY, The Homestead, Hot Springs, Va., March 14-16. Dr. Robert E. Fricke, 102 Second Ave. S.W., Rochester, Minn., Secretary.

AMERICAN SOCIETY OF BIOLOGICAL CHEMISTS, Atlantic City, N. J., April 12-16. Dr. Philip Handler, Duke University, Durham, N. C., Secretary.

AMERICAN SOCIETY FOR EXPERIMENTAL PATHOLOGY, Atlantic City, N. J., April 12-16. Dr. Cyrus C. Erickson, 874 Union Ave., Memphis 3, Tenn., Secretary.

AMERICAN SOCIETY FOR PHARMACOLOGY AND EXPERIMENTAL THERAPEUTICS, Atlantic City, N. J., April 12-16. Dr. Carl C. Pfeiffer, 1853 West Polk St., Chicago 12, Secretary.

CHICAGO MEDICAL SOCIETY ANNUAL CLINICAL CONFERENCE, Palmer House, Chicago, March 2-5. Dr. Maurice M. Hoeltgen, 86 East Randolph St., Chicago, Secretary.

CONFERENCE ON MICROCIRCULATORY PHYSIOLOGY AND PATHOLOGY, University of Texas, Galveston, Texas, April 8-9. Dr. Edward H. Bloch, Western Reserve University School of Medicine, Dept. of Anatomy, Cleveland 6, Chairman.

DALLAS SOUTHERN CLINICAL SOCIETY, Dallas, March 15-18. Dr. T. Haynes Harvill, 433 Medical Arts Bldg., Dallas 1, Texas, Secretary.

EASTERN SECTION, AMERICAN CONGRESS OF PHYSICAL MEDICINE, Newark, N. J., April 10. Dr. H. L. Rudolph, 400 North Fifth St., Reading, Pa., Secretary.

EASTERN SURGICAL SOCIETY, Boston, March 26-27. Dr. J. William Hinton, 130 East 79th St., New York, Secretary.

FEDERATION OF AMERICAN SOCIETIES FOR EXPERIMENTAL BIOLOGY, Convention Hall, Atlantic City, N. J., April 12-16. Dr. M. O. Lee, 2101 Constitution Ave., Washington 25, D. C., Secretary.

ISTHMIAN CANAL ZONE, MEDICAL ASSOCIATION OF THE, El Panama Hotel, Panama City, R. P., March 24-26. Dr. I. Robert Berger, Box "A," Balboa Heights, Canal Zone.

JOHN A. ANDREW CLINICAL SOCIETY, Memorial Hospital, Tuskegee Institute, Ala., April 11-16. Dr. Eugene H. Dibble Jr., John A. Andrew Memorial Hospital, Tuskegee Institute, Ala., Secretary.

MICHIGAN CLINICAL INSTITUTE, Sheraton-Cadillac Hotel, Detroit, March 10-12. Dr. L. Fernald Foster, 606 Townsend St., Lansing 15, Mich., Secretary.

MISSOURI STATE MEDICAL ASSOCIATION, Hotel Jefferson, St. Louis, April 4-7. Dr. E. Royce Bohrer, 634 North Grand Blvd., St. Louis 3, Secretary.

NATIONAL CONFERENCE ON CARE OF THE LONG-TERM PATIENT, Edgewater Beach Hotel, Chicago, March 18-20. Dr. Dean W. Roberts, 615 N Wolfe St., Baltimore 5, Director.

NATIONAL CONFERENCE ON TRICHINOSIS, A. M. A. Headquarters, Chicago, March 1. Dr. S. E. Gould, Wayne County General Hospital, Eloise, Mich., Chairman.

NATIONAL SOCIETY FOR THE PREVENTION OF BLINDNESS, Jefferson Hotel, St. Louis, March 10-12. Dr. F. M. Foote, 1790 Broadway, New York 19, Executive Director.

NEW ORLEANS GRADUATE MEDICAL ASSEMBLY, Municipal Auditorium, New Orleans, March 8-11. Dr. Maurice E. St. Martin, Room 103, 1430 Tulane Ave., New Orleans 12, Secretary.

OHIO STATE MEDICAL ASSOCIATION, Columbus, April 13-15. Mr. Charles S. Nelson, 79 East State St., Columbus 15, Executive Secretary.

PACIFIC NORTHWEST SOCIETY OF PATHOLOGISTS, Amphitheater, Dept. of Pathology, University of Washington School of Medicine, Seattle, April 23-24. Dr. John L. Whitaker, 315 South K St., Tacoma 3, Wash., Secretary.

PACIFIC NORTHWEST SOCIETY OF PLASTIC AND RECONSTRUCTIVE SURGEONS, Seattle, April 3. Dr. E. E. Banfield, Medical Arts Bldg., Tacoma 2, Wash., Secretary.

REGIONAL MEETINGS, AMERICAN COLLEGE OF PHYSICIANS:
TOPEKA, KANS., March 19. Dr. William C. Menninger, 3617 West 6th Ave., Topeka, Kansas, Governor.

SECTIONAL MEETINGS, AMERICAN COLLEGE OF SURGEONS:
FRENCH LICK SPRINGS, Indiana, French Lick Springs Hotel, March 15-17. Dr. Carl H. McCaskey, 20 N. Meridian St., Indianapolis 4, Chairman.
MONTREAL, CANADA, Mount Royal Hotel, March 31-April 2. Dr. Harry S. Morton, 900 Sherbrooke St., West, Montreal, Canada, Chairman.
OMAHA, NEB., Hotel Fontenelle, March 1-4. Dr. Earl A. Connolly, 107 South 17th St., Omaha, Chairman.

SOCIETY OF NEUROLOGICAL SURGEONS, The Waldorf Astoria, New York, April 23-24. Dr. Edgar F. Fincher, Emory University, Ga., Secretary.

SOUTHEASTERN ALLERGY ASSOCIATION, Dinkler-Plaza Hotel, Atlanta, Ga., March 25-27. Dr. Katharine B. MacInnis, 1515 Bull St., Columbia 1, S. C., Secretary.

SOUTHEASTERN SURGICAL CONGRESS, Tutwiler Hotel, Birmingham, Ala., March 8-11. Dr. Benjamin T. Beasley, 45 Edgewood Ave. S.E., Atlanta, Ga., Secretary.

TENNESSEE STATE MEDICAL ASSOCIATION, Nashville, April 18-21. Mr. V. O. Foster, 706 Church St., Nashville 3, Executive Secretary.

UNITED STATES-MEXICO BORDER PUBLIC HEALTH ASSOCIATION, Albuquerque, N. Mex., April 6-9. Sidney B. Clark, 314 U. S. Court House, El Paso, Texas, Secretary.

WESTERN SOCIETY OF ELECTRO-ENCEPHALOGRAPHY, Del Monte Lodge, Pebble Beach, Calif., March 7-8. Dr. Sylvester N. Berens, 902 Boren Ave., Seattle, Secretary.

FOREIGN AND INTERNATIONAL

ASSOCIATION OF SURGEONS OF GREAT BRITAIN AND IRELAND, Leeds, England, May 13-15, 1954. Dr. Henry W. S. Wright, 45 Lincoln's Inn Fields, London W.C.2, England, Honorary Secretary.

BRITISH MEDICAL ASSOCIATION, Glasgow, Scotland, July 1-9, 1954. Dr. A. Macrae, B.M.A. House, Tavistock Square, London, W.C.1, England, Secretary.

CANADIAN MEDICAL ASSOCIATION, Vancouver, B. C., Canada, June 14-18, 1954. Dr. T. C. Routley, 244 St. George St., Toronto 5, Ontario, Canada, General Secretary.

CONFERENCE OF INTERNATIONAL UNION AGAINST TUBERCULOSIS, Madrid, Spain, Sept. 26-Oct. 2, 1954. Secretariat, Escuela de Tisiologia, Ciudad Universitaria, Madrid, Spain.

CONGRESS OF INTERNATIONAL ASSOCIATION FOR THE PREVENTION OF BLINDNESS, New York, N. Y., U. S. A., Sept. 12-17, 1954. Professor Franceschetti, 2 Avenue Mirimot, Geneva, Switzerland, Secretary-General.

CONGRESS OF INTERNATIONAL ASSOCIATION FOR THE STUDY OF THE BRONCHI, Geneva, Switzerland, June 5-6, 1954. Professor A. Montandon, Clinique Universitaire d O.R.L., Hôpital Cantonal, Geneva, Switzerland, Chairman.

EUROPEAN SOCIETY OF CARDIOVASCULAR SURGERY, Edinburgh, Scotland, July 9-10, 1954. For information address: Mr. A. J. Slessor, Department of Surgery, University New Building, Edinburgh 8, Scotland.

HEALTH CONGRESS OF THE ROYAL SANITARY INSTITUTE, Scarborough, England, April 27-30, 1954. Mr. P. Arthur Wells, Royal Sanitary Institute, 90 Buckingham Palace Road, London, S.W.1, England, Secretary.

INTERNATIONAL ANESTHESIA RESEARCH SOCIETY, Los Angeles, Calif., U. S. A., Oct. 10-14, 1954. For information write: Dr. T. H. Seldon, 102-110 Second Avenue S.W., Rochester, Minn., U. S. A.

INTERNATIONAL CANCER CONGRESS, Sao Paulo, Brazil, July 23-29, 1954. Prof. A. Prudente, 171 rua Benjamin Constante, Sao Paulo, Brazil, President.

INTERNATIONAL CONFERENCE ON THROMBOSIS AND EMBOLISM, Basle, Switzerland, July 20-24, 1954. Dr. W. Merz, Chief Medical Officer, Gynecological Clinic, University of Basle, Basle, Switzerland, Hon. Secretary.

INTERNATIONAL CONGRESS OF CLINICAL PATHOLOGY, Washington, D. C., U. S. A., Sept. 6-10, 1954. Dr. Robert A. Moore, Washington University School of Medicine, St. Louis 10, Mo., U. S. A., Chairman, Committee on Arrangements.

INTERNATIONAL CONGRESS ON DISEASES OF THE CHEST, Barcelona, Spain, Oct. 4-8, 1954. Mr. Murray Kornfeld, 112 East Chestnut St., Chicago 11, Ill., U. S. A., Executive Secretary.

INTERNATIONAL CONGRESS ON GROUP PSYCHOTHERAPY, Toronto, Ont., Canada, Aug. 12-14, 1954. Dr. J. L. Moreno, Room 327, 101 Park Ave., New York 17, N. Y., U. S. A., Director of Organizing Committee.

INTERNATIONAL CONGRESS ON GYNECOLOGY AND OBSTETRICS, Geneva, Switzerland, July 26-31, 1954. Dr. H. de Wateville, Maternité Hôpital Cantonal, Geneva, Switzerland, President.

INTERNATIONAL CONGRESS OF HEMATOLOGY, Paris, Sept. 6-11, 1954. Dr. Jean Bernard, 86 rue d'Assas, Paris 6^e, France, Secretary.

INTERNATIONAL CONGRESS OF THE HISTORY OF MEDICINE, Rome and Salerno, Italy, Sept. 13-20, 1954. For information write: Segreteria XIV Congresso Internazionale di Storia della Medicina, Istituto di Storia della Medicina, Citta Universitaria, Rome, Italy.

INTERNATIONAL CONGRESS OF HYDROCLIMATISM AND THALASSOTHERAPY, Dubrovnik, Yugoslavia, May 8-16, 1954. Prof. C. Plavsic, Zeleni venac 1, Belgrade, Yugoslavia, Secretary General.

INTERNATIONAL CONGRESS OF INDUSTRIAL MEDICINE, Naples, Italy, Sept. 13-19, 1954. Professor Scipione Accuri, Director, Institute of Industrial Medicine Policlinico, Naples, Italy, Chairman, Organizing Committee.

INTERNATIONAL CONGRESS OF INTERNAL MEDICINE, Stockholm, Sweden, Sept. 15-18, 1954. Professor Anders Kristenson, Karolinska Sjukhuset, Stockholm 60, Sweden, Secretary-General.

INTERNATIONAL CONGRESS OF INTERNATIONAL COLLEGE OF SURGEONS, São Paulo, Brazil, April 26-May 2, 1954. Dr. Max Thorek, 1516 Lake Shore Drive, Chicago, Ill., U. S. A., Secretary-General.

INTERNATIONAL CONGRESS ON MENTAL HEALTH, University of Toronto, Toronto, Ontario, Canada, Aug. 14-21, 1954. For information write: Executive Officer, International Congress on Mental Health, 111 St. George St., Toronto, Ontario, Canada.

INTERNATIONAL CONGRESS OF MILITARY MEDICINE AND PHARMACY, Buenos Aires, Argentina, April 21-28, 1954. Direccion General de Sanidad Militar, Pozos 2045, Buenos Aires, Argentina.

INTERNATIONAL CONGRESS OF NUTRITION, Amsterdam, Netherlands, Sept. 14-18, 1954. For information write: Dr. M. van Eekelen, Centraal Instituut voor Voedingsonderzoek T.N.O., 61 Catharynesingel, Utrecht, Netherlands.

INTERNATIONAL CONGRESS OF OPHTHALMOLOGY, University of Montreal and McGill University, Montreal, Canada, Sept. 9-11, 1954, and Waldorf-Astoria, New York, N. Y., U. S. A., Sept. 12-17, 1954. Dr. William L. Benedict, 100 First Avenue Building, Rochester, Minn., U. S. A., Secretary-General.

INTERNATIONAL CONGRESS OF ORTHOPEDIC SURGERY AND TRAUMATOLOGY, Berne, Switzerland, Aug. 30-Sept. 3, 1954. For information write: Professor M. Dubois, Isle-Hospital, Berne, Switzerland.

INTERNATIONAL CONGRESS OF PSYCHOLOGY, Montreal, Canada, June 7-12, 1954. For information write: Prof. H. S. Langfeld, International Union of Scientific Psychology, Eno Hall, Princeton University, Princeton, N. J., U. S. A.

INTERNATIONAL CONGRESS FOR PSYCHOTHERAPY, Zurich, Switzerland, July 21-24, 1954. Dr. H. K. Fierz, Theaterstrasse 12, Zurich 1, Switzerland, Secretary-General.

INTERNATIONAL CONGRESS OF THE SOCIEDAD DE MÉDICOS INTERNOS, Residentes y Becarios del Instituto Nacional de Cardiología de Mexico, Acapulco, Mexico, April 21-24, 1954. For information address: Dr. Jorge Soberón Acevedo, Avenida, Cuauhtemoc No. 300, Mexico, D. F., Mexico.

INTERNATIONAL GERONTOLOGICAL CONGRESS, London and Oxford, England, July 12-22, 1954. Prof. R. E. Tunbridge, General Infirmary, Department of Medicine, The University, Leeds, England, President.

INTERNATIONAL INSTITUTE ON CHILD PSYCHIATRY, Toronto, Canada, Aug. 13-14, 1954. Miss Helen Speyer, International Association for Child Psychiatry, 1790 Broadway, New York 19, N. Y., U. S. A., Executive Officer.

INTERNATIONAL POLIOMYELITIS CONGRESS, Rome, Italy, Sept. 6-10, 1954. Mr. Stanley E. Henwood, 120 Broadway, New York 5, N. Y., U. S. A., Executive Secretary.

ARMY

Modified Affiliation Plan for Army Hospitals.—More than 50 medical colleges and large civilian hospitals throughout the United States have entered into an informal agreement with the Army Surgeon General whereby each will furnish a limited number of highly qualified doctors and dentists for key specialist assignments in a 1,000-bed general hospital for employment only in time of a major national emergency.

This agreement is a modification of the reserve hospital plan used in both world wars under which a formally organized group was required to conduct military training and secure a full complement of commissioned officers. The modified arrangement permits the hospital or medical school to retain these key professional staff members, selected for the unit for several months after the initial impact of the emergency. These personnel will not be required until the reserve hospital units are called to active duty and the administrative and housekeeping personnel are organized and trained.

The modified affiliation program interferes in no way with the traditional establishing of reserve hospital units by those institutions desiring to do so. In fact, a school or hospital may have both types of participation in the Army's plans for medical national defense. Members of school faculties or hospital staffs who wish to continue in reserve activities at those institutions where only the modified affiliation program exists may associate themselves with a local reserve troop program unit or join the medical section in the reserve school. The modified affiliation units will be members of the Army of the United States. The Adjutant General of the Army has reserved the numbers utilized by the sponsored units in previous conflicts for reissue as appropriate.

"Experience in World Wars I and II and the Korean conflict has shown that professional specialists need only short periods of military instruction before engaging in their primary Army duties," the Surgeon General said in explanation of the modified affiliation program.

Although the program followed in those wars and in Korea was generally satisfactory, budgetary restrictions, mounting overhead costs, lack of space, shortages of personnel in certain categories, and increased civic responsibilities imposed on both hospitals and staff members were among the major factors that brought about the new plan. At the time the Army activates the headquarters and administrative complement of the modified affiliation unit for training in military procedures, the institution would be requested to supply only a chief nurse and one other nurse, two Medical Corps captains and one Dental Corps captain, and one dietitian first lieutenant. Several months later the institution would be asked to select members of its professional staff and have them prepare applications for commissions in the Army of the United States. The appropriate Army commander would process the appointments, publish necessary orders, and arrange for required military indoctrination so timed as to allow these officers to join the unit by the target date.

The colleges or hospitals in this "gentlemen's agreement" will not be required to provide a formal organization, appoint officers, nor agree to conduct training programs in order to be accepted in the plan. The modified affiliation plan, however, does not permit an officer to use it as a basis for military deferment if he should be called separately for active duty prior to the activation of the sponsored unit.

Three-Year Residency in Anesthesiology.—The Army Medical Service residency program in anesthesiology will be increased in term to three years beginning July 1 to give candidates additional training; it has been announced by Major Gen. George E. Armstrong, Surgeon General.

The new plan provides for the two years of clinical training required for American Board of Anesthesiology certification and an additional year of research and development training coordinated with the basic sciences in anesthesiology.

Selected Medical Corps officers will spend their first year of the three-year residency at Walter Reed Army Medical Center, Washington, D. C. The second year will be presented at the Army Medical Service Graduate School, Walter Reed Army Medical Center, and will be devoted to research and development. The last year of residency will be spent at one of four Army hospitals, and the candidates will have a summation of training with clinical and teaching experience. The four hospitals to be utilized in the program are Brooke Army Hospital, Fort Sam Houston, Texas; Fitzsimons Army Hospital, Denver; Letterman Army Hospital, San Francisco; and Walter Reed Army Hospital, Washington, D. C.

NAVY

Surgeon General Returns from Far East.—The Surgeon General, Rear Adm. Lamont Pugh, has completed a 20-day informal visit to Navy Medical Department activities in the Pacific Northwest, Aleutians, Korea, Japan, Guam, Kwajalein, Midway, and Hawaii, and has returned to Washington. The purpose of this trip was to meet with Medical Department personnel in the field, to hear and to discuss their problems, to explain current Medical Department policy, and to obtain from the actual operating forces, information on which to base future policy. The Surgeon General addressed Medical Department personnel at the Naval Hospital, Yokosuka, Japan, those assigned to the Third Marine Division in Japan, the staff of the hospital ship Repose, and those assigned to the First Marine Division in Korea.

VETERANS ADMINISTRATION

Vacancies at Various Hospitals.—Various Veterans Administration hospitals throughout the country urgently need social workers, dietitians, biochemists, x-ray and medical technicians, and therapists of all types. Applicants are requested to contact the personnel office at any VA hospital, regional office, center, or domiciliary for information or to write directly to the Veterans Administration, Washington, D. C.

Annual beginning salaries and salary ranges for these positions are: therapists (educational, corrective, manual arts, physical, and occupational), \$3,410 to \$5,060; x-ray technicians, \$3,175 to \$3,795; medical technicians, \$3,175 to \$4,205; social workers, \$4,205 to \$5,940; dietitians, \$3,410 to \$5,940; and biochemists, \$4,205 to \$7,040. Most of these positions require college training, and social workers need graduate training. For the higher paying positions appropriate work experience is needed. X-ray and medical technician applicants may qualify on experience alone.

Annual Institute in Psychiatry and Neurology.—Under the sponsorship of the Veterans Administration Hospital, Lyons, N. J., the New Jersey Neuropsychiatric Association, and the New Jersey District Branch of the American Psychiatric Association, the annual institute in psychiatry and neurology will be held at the hospital, April 21. Drs. Daniel Blain, Washington, D. C., Stephen P. Jewett, New York, and Harvey T. Tompkins, Washington, D. C., will serve as moderators for the following programs: "Emotional Deprivation in Infancy and Its Implications in Child Psychiatry," Lauretta Bender, New York; "The Administrator's Place in Psychiatry," Arthur P. Noyes, Norristown, Pa.; "Sexual Psychopathology and Crime," Benjamin Karpman, Washington, D. C.; and "The Origin of Human Movement," Temple S. Fay, Philadelphia. Dinner, at 7 p. m., will be followed by a presentation entitled "Failures in Psychotherapy," by Dr. Leo H. Bartemeier, Detroit. Military personnel and full-time VA personnel will be exempt from the registration fee of \$1, which will include a copy of the proceedings of the institute. Additional information may be obtained from Dr. Crawford N. Baganz, manager of the hospital.

FOREIGN LETTERS

BRAZIL

Intracranial Cysticercosis.—Dr. Antonio França Netto presented to the Associação Paulista de Medicina a report on 47 patients with intracranial cysticercosis treated in the São Paulo Hospital das Clínicas from Jan. 1, 1946, to Dec. 31, 1952. These patients were observed among 1,636 neurological patients of all kinds and represent 2.85% of the larger group. The age distribution by 10-year groups showed a maximum concentration in the first decade of life (no patient was less than 2 years old). The rest of the patients were fairly evenly distributed between the ages of 10 and 70 years. The diagnosis could not be proved in two cases. In 5 of the remaining 45 patients the diagnosis was based on a positive Weinberg's reaction in the blood and on the presence of eosinophilia, with concomitant intestinal teniasis in one, and was therefore considered incomplete. The diagnosis was confirmed by postmortem examination in five cases, and by operation in one. In 26 the diagnosis was based on alterations in the cerebrospinal fluid; in 2 on the finding of intracranial calcifications; and in 6 on both. Although changes in the spinal fluid occurred in 37 patients, they were sufficient to establish the diagnosis in only 32. Alterations in the spinal fluid sufficient to permit the establishment of the diagnosis were a positive Weinberg's reaction and the presence of eosinophils. The latter were present in 21 patients and a positive Weinberg's reaction in 32. In 11 hypoglycorrhachia was observed. In relation to the clinical findings there were 25 cases of intracranial hypertensive syndrome; 12, of intracranial focal neurological syndrome; 7, of convulsive syndrome (of which 4 were focal); 2, of radiculomedullary syndrome; and 1, of a mixed form (medullary, but having a secondary intracranial hypertensive syndrome). The disease ran a favorable course, with improvement in 24 patients; 9 were discharged unimproved. The condition of one became worse in the hospital. In three it was impossible to know the exact condition at the time of discharge, and in eight the course was unfavorable, ending in death. In four of the fatal cases the diagnosis was established during life and in four at autopsy.

Intestinal Perforation in Premature Infants.—At a meeting of the Associação Paulista de Medicina Drs. Pedro Refinetti and Virgílio Carvalho Pinto of the São Paulo Filomena Matarazzo Maternity Hospital reported 9 premature infants who died in that hospital within 53 days. During that period there was always at least one sick premature infant in the hospital nursery. The disease usually began with a slight gastrointestinal disorder. In five of the infants the subsequent symptoms were predominantly abdominal and in four predominantly pulmonary. Of the five with abdominal symptoms, three were operated on and showed perforations in the jejunum, ileum, and ascending colon respectively. The authors believe that a single causative agent was probably responsible in the five cases. All infants weighing more than 2 kg. were almost free of any disease. The authors concluded that a combination of the increased intra-intestinal pressure and the presence of the ulcerations frequently observed in premature infants caused the perforations.

High Direct Cephalic Presentation of the Fetus.—Drs. Oswaldo Lacrete and Bernardo Blay (*Rev. gynec. e obst.* 47:553, 1953) reviewed 15 cases of high direct cephalic presentation of the fetus in women attended from 1949 to 1952 at the Leonor de Barros Maternity Hospital of the city of São Paulo. In some cases, the fetal head enters the superior strait of the pelvis with the sagittal suture oriented in the anteroposterior diameter and remains in this position. This presentation presents a special problem about which little appears to have been written. Their 15 cases were observed in 25,514 deliveries (a rate of 0.058%). Eight of the women were multiparas and seven primiparas. Nine fetuses were of more than average weight

(one weighed 5.06 kg. and one 4.26 kg.). According to German authors, the early rupture of the membranes is a causative factor in high direct cephalic presentation. In the present series premature rupture was observed in six.

DENMARK

Control of the Drugs of Addiction.—The Danish Minister for Internal Affairs appointed a committee in November, 1950, to inquire into the medical and administrative problems raised by morphine and other euphoria-producing drugs. The findings of this committee are published in *Ugeskrift for Læger* for Nov. 5 and 12, 1953. The committee finds that, in spite of measures taken against these drugs in recent years, there has been no reduction in their consumption. Recent investigations have demonstrated the futility of attempting to cure addicts in an advanced stage of addiction. It has hitherto been very difficult to catch addicts among physicians at a time when their addiction is still curable. The part played by the theft or smuggling of drugs of addiction is comparatively small. The most important factor is the medical prescription—genuine or forged. Although the forging of prescriptions may be on the increase, genuine prescriptions still play a very important part and reflect conditions amenable to reform. Physicians should be encouraged to cooperate with pharmacists and to study their reports to the public health authorities. Voluntary cooperation among physicians should enable them to deal with the addict who goes from one physician to another and obtains small quantities of drugs from each. The supply of heroin could be completely cut off without any new legislative measure by the simple device of refusing to issue any import license for it. The amphetamines are more dangerous because their sale has not hitherto been restricted by law. It may not be advisable to forbid the use of amphetamine solutions in hospitals, but physicians should not prescribe them in their office practice. In England, Switzerland, Sweden, and Norway physicians abusing their right to prescribe drugs may have this right withdrawn in respect of drugs of addiction. At present there is no such check on physicians in Denmark, but the committee would like to see it adopted. Physicians should be urged to be just as careful in prescribing drugs of addiction for themselves as for their patients, and when the public health authorities have evidence of dangerous prescribing in a given case, the physician in question should be made to keep a special record of his prescription of such drugs, with the names and addresses of his patients and why they were thus treated.

Artificial Insemination.—Since 1948 Denmark, Finland, Norway, and Sweden have been considering the problem of legal regulation of artificial insemination. Although minor national differences of legal or social importance have prevented the tentative drafting of uniform laws suitable for Scandinavia as a whole, all the special committees from these countries have agreed in not recommending laws directed against artificial insemination in principle. They have also agreed on the need for laws providing for the legal status of the offspring of insemination when the mother's husband has consented to this action. The composition of each national committee has also been much the same in the different countries, with the legal and medical professions well represented on each. In Denmark the committee includes two physicians and three lawyers, and two of the latter are women.

The report of the Danish committee has been given a mixed reception. Speaking at a meeting of the Danish Medical Association in September, 1953, Dr. Mogens Fenger expressed great concern over the responsibility put on the medical profession for the proposed practice of artificial insemination. He noted that only the Danish committee has proposed laws governing the insemination of unmarried women. It would seem that the

physician alone will have to decide whether an unmarried woman is qualified to educate and maintain her child. How, Dr. Fenger asked, could a gynecologist, after consultation with the unmarried woman's regular doctor, give useful advice without the assistance of a psychiatrist? It is also proposed that the choice of a suitable donor should devolve on the mother's doctor. How, as he looks about him, can a doctor be sure that his choice of donor is wise and based on a truly intimate knowledge of his qualifications for this function? Dr. Fenger commented on the provision that it is incumbent on a physician to put a reasonable limit on the number of inseminations to be required of one and the same donor who should, presumably, not be the physician himself. Dr. Fenger also remarked that the committee had omitted to provide for the unmarried man who wants a child produced by insemination.

ITALY

Hematology Convention.—The 11th national convention of the Italian Society of Hematology was held at the medical clinic of the University of Rome, May 10 and 11, 1953. Professor Di Guglielmo, Rome, was the chairman. Professor Heilmeyer discussed the treatment of leukemia with tetraethylammonium (TEM). He recalled briefly the chemical and pharmacological characteristics of the new preparation and reported on his experimental and clinical studies. The drug did not have any particular action on the red blood cells of rats that were intoxicated by it, but it did influence in proportion to the doses administered, the leukocytes and especially the neutrophils and the platelets. With massive doses, the number of neutrophils decreased markedly and the platelets often disappeared. The marrow revealed hypoplasia and the spleen reduction of the lymph follicles and a lively movement of the reticulohistocytary cells. The inhibiting action of tetraethylammonium on the leukocytes and platelets seems to be easily reversible.

The administration of the drug to persons with leukemia is followed by a pronounced decrease in the number of leukocytes and platelets. The drop in the number of leukocytes may often continue for some time, especially if maintenance doses are given. The decrease in the number of platelets may cause hemorrhage and necessitate interruption of the therapy and the institution of symptomatic treatment. A second course of tetraethylammonium is usually as effective as the first. Some patients tolerated it better than irradiation therapy and urethane; many preferred it; and only a few were not satisfied with it. Professor Heilmeyer is in favor of using tetraethylammonium in leukemia on a wide scale provided proper precautions are taken.

Professor Fonio reported on clot retraction and discussed the results of the experiments he and his associates made to study the importance of platelets in this phenomenon. He discussed the various aspects of the physiology of the platelets and demonstrated that they are greatly increased in persons who live at high altitudes. He also showed that an altered function of the platelets may produce a hemophilia-like syndrome that often remains undiagnosed. He recalled how easily the clot retracts at high temperatures and suggested that the use of great heat in the treatment of hemorrhage in persons with hemophilia will produce a lasting hemostasis.

Professor Juergens of Basel reviewed the present position of bishydroxycoumarin (Dicumarol) products in anticoagulant therapy and said that vitamin K₁ is an antidote to the hemorrhagic phenomena resulting from treatment with bishydroxycoumarin. His research work dealt mainly with Marcoumar and Konakion. Marcoumar is 3-(1'-phenyl-propyl)-4-hydroxycoumarin. It lowered the concentration of the 7th factor and the prothrombin in experimental animals, but the 5th factor was not changed. This effect is obtained by administering less (or slightly more) than 1 mg. of Marcoumar per kilogram of body weight, depending on the species of animal tested, and may persist for more than 10 days. The toxic action of the substance depends on the intensity of its action on the coagulation.

Konakion (synthetic vitamin K₁) was active not only on hypoprothrombinemia caused by bishydroxycoumarin, Marcoumar, or other similar substances but also on severe hypoprothrombinemia secondary to removal of the liver. The fact that vitamin K₁ in doses of 50 mg. per kilogram of body weight can induce

regeneration of the coagulation factors, the prothrombin, and the 7th factor, even when the liver has been removed, has both theoretical and practical importance. These factors were found in the blood of animals from which the liver had been removed 6 to 10 hours after the administration of Konakion. Professor Juergens concluded that Marcoumar may be of great clinical value and that all the accidents that it may cause are rapidly controlled with vitamin K₁.

Professor Villa, with the collaboration of Drs. Polli and Bussi, studied the normal and abnormal structure of nuclei of the blood cells at rest and during growth and division. They showed that the nucleus of the erythrocytes in vertebrates is included in the group that biologists define as "nucleus with clumps and filaments." The nuclear characteristics observed during the evolution of erythroblasts consist of the early emergence of masses that give a positive Feulgen reaction in the nucleus at rest. The mitotic chromosomes of the erythroblasts give a highly positive Feulgen reaction. In pathological states the megaloblasts in the initial phase of maturation present chromosomes that are long and thin and give a slightly positive Feulgen reaction; in the "metaphase" phase they are contracted and give a "Feulgen reaction." The speakers found no significant differences in the amounts of nucleic acid in normal and abnormal leukocytes, or between the amino acids present in the nuclei, the isolated chromosomes, and the nuclear histone of normal and leukemic cells.

Studies on the lipid fractions of the entire leukocytes and of normal and abnormal nuclei of leukocytes of human beings and horses revealed no marked differences between the normal leukocytes of the two species, but marked differences between normal and abnormal cells in men. This difference is noted especially in the nuclei. The speakers studied the structure of the nuclei of living cells, chiefly blood cells, and found an excess of compact chromatin in the leukemic elements by means of microstratigraphic investigations that aimed at defining the spatial distribution of compact chromatin in the nucleus of normal and leukemic lymphocytes. Studies of the cytochemical aspects of the structure of the blood cells indicated the importance and difficulty of the study of cytoenzymes.

NORWAY

Misguided Public Authorities and the Insane.—At a recent public meeting, Dr. Karl Evang, who heads the Public Health Service in Norway, spoke more in sorrow than in anger (but with plenty of both) about the attitude of central and local public authorities who compete with each other in claiming lack of funds and disclaiming the ability to meet the calls of the Public Health Service regarding beds for patients with chronic mental diseases. In 1948, Dr. Evang budgeted for an annual expenditure by the central government of 50 million kroner in the coming five year period for the establishment of various types of hospitals. In 1950 the actual sum spent was 18,800,000; in 1951 it was 22,800,000; and in 1952 it was 37,900,000. It was not till 1953 that the sums spent approached the sums for which he had budgeted. He admits that the need for more housing by the general public has been the worst obstacle to the building of medical institutions.

At present the asylums in Norway can accommodate only half the total number (about 16,500) of insane persons needing some form of treatment. Some of them are boarded out in private homes (farms), and though this system is not without merits, it would be well, in Dr. Evang's opinion, to reduce the number of such private boarders by about half. To do so, more asylum accommodation must be provided. More important than the lack of funds for this purpose during the postwar period has been the shortage of material and labor. Dr. Evang enlivened this rather somber picture by an account of the campaign against the venereal diseases which in the course of the last five years has effected a reduction of expenses to less than one quarter of what they were earlier. The number of patients with gonorrhea is at present only one-third of the lowest figure for the prewar period, and the number of those with syphilis is three-quarters of the average prewar figures, giving an all-time low of about 300 new cases of syphilis for all Norway in 1952.

CORRESPONDENCE

THE CORONER SYSTEM

To the Editor:—Dr. Turkel's article "Merits of the Present Coroner's System" was excellent (THE JOURNAL, Nov. 21, 1953). Although I have never held public office, I have been associated with the coroner's office of Detroit for 41 years. In the same issue, an editorial, which states the real problem very clearly, ends with the unfortunate sentence, "Although Dr. Turkel has not submitted convincing evidence that it is better to keep the office in the county politics than to put it under the merit system, he has shown that it is possible to do good work under great handicaps." This reexpresses an almost universal misconception of the truth. In Wayne County, Michigan, the county auditors have always usurped the right to appoint the medical examiners, because the auditors hold the purse strings. The coroners have never been allowed to exercise that prerogative that the state law expressly gives them. The county auditors have never, in the past 41 years, appointed a properly trained medical examiner to serve Wayne County. The appointments have always been made on the basis of potential political patronage.

The act recently passed by the Michigan legislature, if implemented by a vote of the people, will abolish the office of coroner and confirm the power of the auditors to make the appointment of medical examiners part of the county patronage. The office will then become a branch of the prosecuting attorney's machine. The other alternative under this law is that the state police will have jurisdiction. The value of the coroner under Anglo-Saxon law has always been that his office is independent of any prosecuting or police agency. He is not dependent for his job on a prosecutor who is out to make a record of a high percentage of convictions, nor is he under the police who get "merit" counts for preparing successful cases against suspects. If you think that pressure from prosecutors and police to influence the findings of medical examiners is theoretical, let me assure you that 41 years' experience in these matters is quite to the contrary. A medical examiner should be protected in his right to determine the cause of death. His duty ends there. He is not a prosecutor, and he is not a policeman. He should not be under obligation to or pressure from either.

The self-serving interests that are trying to take the matter "out of politics" are really concerned with abolishing the coroner's independent position and strengthening the local political machine. Like all such propaganda the objectives as publicized seem very pious to the uninitiated. Whether you call him a coroner or medical examiner makes little difference. The important objective is that he should have the powers that Anglo-Saxon law has given him almost since the Magna Charta and that he should be his own man, free from the pressure of prosecutors or homicide squads. All physicians know what sort of a system should be established. The voters want a good system, but machine politicians have sold them something quite different. The medical examiners or coroners, whichever name is selected, should be appointed on the basis of clear-cut qualifications laid down in a properly worded statute. They should be appointed for a relatively long term so that the matter is taken out of changeable political climates, and they should be chosen by the circuit judges not by prosecutors or policemen and not as part of a party ticket at county elections.

PLINN F. MORSE, M.D.

Director, Department of Laboratories and Research,
Harper Hospital
Detroit 1.

To the Editor:—The article by Dr. Turkel (*J. A. M. A.* 153: 1086 [Nov. 21] 1953) and the editorial in the same issue on the coroner system and the medical examiner are timely but not complete. In Los Angeles County we have a coroner and the system has been very successful, even more so than the figures given in Dr. Turkel's article would indicate. This is

because competent full-time autopsy surgeons and a competent toxicologist are attached to the office. They are all Civil Service appointees. The office has the full cooperation of the sheriff's office, police departments of the many cities in this county, the district attorney's office, the morticians, and the medical profession. Furthermore, this office has a better set of state laws to work with than those in most other states.

There has been much discussion about the merits of the two systems, but to be successful either system must have adequate state laws. The law must give the officials enough authority to proceed in a case. In some states, they have to ask permission for an autopsy, and often, when an autopsy is most needed, the relatives refuse. The law must require that a properly trained pathologist and toxicologist be employed. In counties too small to justify such an expenditure, the state should make such services available or one unit could be employed jointly by two or more counties. No matter what his title is or whether he is appointed or elected, success or failure depends on the quality of the person holding the position. If he is efficient and supported by adequate laws, then and only then can a coroner do good work.

J. W. ROBINSON, M.D.
2686 Locksley Pl.
Los Angeles 39.

To the Editor:—In reading your editorial comment (*J. A. M. A.* 153:1100 [Nov. 21] 1953) concerning the article by Dr. Turkel in the same issue, I wish to call attention to the fact that both the coroner of Los Angeles and the coroner of San Francisco are appointed from Civil Service lists and that no coroner in the state of California runs for election on a party ticket. The concept of government in California is such that all public officials below the state level are either Civil Service appointees or elected nonpartisan candidates. It is encouraging to see some evidence that the name-calling period may be over and that all parties interested in good government can join forces.

V. L. WALLAGE
Chief Deputy Coroner
Hall of Justice
Los Angeles 12.

SOCIAL SECURITY FOR PHYSICIANS

To the Editor:—A menacing specter is on the horizon with the extension of social security to include the medical profession by the "benefactors" in Washington. As was pointed out before, physicians do not retire at the age of 65. The long, arduous, and expensive training of a physician does not make it economically practicable for him to retire at such an early age. Why should a physician past 65 begin to contribute to a pension scheme, if he has no intention of ever retiring? The minimum of \$400 a year is ridiculous, for if anyone makes this amount, or even double, only a politician can figure out how he can make both ends meet and pay 2.5% to the government on it. An intern or resident is lucky if he makes that much, and it is stark irony to subject him to such a tax.

An unskilled Mexican laborer told me that he makes \$17 a day. According to recent report in *Medical Economics*, some physicians on Park Ave. in New York City do not make that much, and I am sure that there are quite a few others throughout the country who put service before remuneration and do not earn that much. The idealism of service to humanity, traditional with medicine, does not enter the sphere of the labor unions, but in this case we are classed with them, much to our disadvantage. Even Bismarck with his pension plan, much decried in the past as socialistic, did not envision such radical extension of the scheme.

HANS SCHROEDER, M.D.
450 Sutter St., San Francisco 8.

COUNCIL ON MEDICAL EDUCATION AND HOSPITALS

ADDITIONAL HOSPITALS REGISTERED

The following hospitals were registered by the Council on Medical Education and Hospitals of the American Medical Association at its meeting in Chicago, Feb. 5, 1954:

U. S. Army Hospital, Ft. McClellan, Ala.
U. S. Army Hospital, Flagstaff, Ariz.
St. Joseph's Hospital, Nogales, Ariz.
U. S. Army Hospital, Barstow, Calif.
U. S. Army Hospital, Lompoc, Calif.
Memorial Hospital, Modesto, Calif.
Needles Municipal Hospital, Needles, Calif.
Porterville State Hospital, Porterville, Calif.
Balboa Hospital, San Diego, Calif.
U. S. Army Hospital, San Pedro, Calif.
East Hartford Hospital, East Hartford, Conn.
Miami Heart Institute, Miami Beach, Fla.
Santa Rosa Hospital, Milton, Fla.
Lily White Hospital, Tampa, Fla.
Douglas-Coffee County Hospital, Douglas, Ga.
Dodge County Hospital, Eastman, Ga.
Mary Lorton Nursing Home, Belleville, Ill.
Kenmore House, Chicago
Veterans Administration Research Hospital, Chicago
Gibson Community Hospital, Gibson City, Ill.
Richland Memorial Hospital, Olney, Ill.
Allen's Baptist Sanitarium, Robinson, Ill.
Grundy County Memorial Hospital, Grundy Center, Iowa
Ellinwood District Hospital, Ellinwood, Kan.
Kiowa District Hospital-Clinic, Kiowa, Kan.
Phillips County Community Hospital, Phillipsburg, Kan.
Lutheran Hospital, Scott City, Kan.
Donaldsonville General Hospital, Donaldsonville, La.
Montebello State Hospital, Baltimore
Clinical Center, National Institutes of Health, Bethesda, Md.
Veterans Administration Hospital, Boston
Veterans Administration Hospital, Brockton, Mass.
Veterans Administration Hospital, Ann Arbor, Mich.
St. Luke's Infirmary, Duluth, Minn.
Franklin County Memorial Hospital, Meadville, Miss.
U. S. Army Hospital, Camp Crowder, Mo.
Roberts-Worley Clinic-Hospital, Sweet Springs, Mo.
Gunn Clinic-Hospital, Versailles, Mo.
Glacier County Memorial Hospital, Cut Bank, Mont.
Granite County Memorial Hospital, Phillipsburg, Mont.
Schuyler Memorial Hospital, Schuyler, Nebr.
U. S. Army Hospital, Albuquerque, N. Mex.
Fort Stanton Medical Center, Fort Stanton, N. Mex.
Madison Park Hospital of Adelphi College, Brooklyn
Yancey Hospital, Burnsville, N. C.
Gravelly Sanatorium, Chapel Hill, N. C.
Spastics Hospital, Charlotte, N. C.
Union Memorial Hospital, Monroe, N. C.
Veterans Administration Hospital, Salisbury, N. C.
St. Gerard's Community Hospital, Hankinson, N. Dak.
Community Hospital, Rolette, N. Dak.
St. Charles Hospital, Toledo, Ohio
Santiam Memorial Hospital, Stayton, Ore.
Colver Hospital, Colver, Pa.
Belvedere General Hospital, Pittsburgh
Willow Grove Hospital, Willow Grove, Pa.
West River Crippled Children's Hospital, Hot Springs, S. Dak.
Crippled Children's Hospital and School, Sioux Falls, S. Dak.
Bellville Hospital, Bellville, Texas
New Braunfels Hospital, New Braunfels, Texas
Southmore Hospital and Clinic, Pasadena, Texas
U. S. Army Hospital, Texarkana, Texas
Shipman Clinic-Hospital, Vernon, Texas
U. S. Army Hospital (Proving Ground), Tooele, Utah
U. S. Army Hospital (Ordnance Depot), Tooele, Utah
U. S. Army Hospital, Camp Hanford, Wash.
Valley Convalescent Hospital, Charleston, W. Va.
St. Joseph's Memorial Hospital, Hillsboro, Wis.
Johnson County Memorial Hospital, Buffalo, Wyo.
Campbell County Memorial Hospital, Gillette, Wyo.
Adjuntas Health Center, Adjuntas, P. R.

BUSINESS PRACTICE

This is the second in a series by these authors on various phases of business practice. In this article the authors suggest physicians collect their own fees.—ED.

COLLECTION OF FEES

*Chester Porterfield
and
Geoffrey Marks, Seattle*

More words have been written about collection procedures than any other single aspect of medical practice administration. More schemes have been devised to "bring in the money" than any physician could possibly apply. More misunderstandings of the true nature of the collection problem have been fostered by their operation and more disappointments incurred by their failure than we could possibly enumerate. Customarily the blame for failure is placed by the frustrated physician on his secretary, in getting out statements; on the collection follow-up system, for not producing automatic results; on the collection agency, for its inability to track down and collect from unwilling patients; and most frequently, on the ungrateful and dishonest patients themselves.

IS THE SECRETARY TO BLAME?

When a doctor blames his secretary for not quoting the fee or making payment arrangements, he forgets that he has so often told the patient who asks about these things, "Don't bother about that now; we just want to make you well," or, "Don't worry about the bill; my charges are reasonable." For this reason, when the patient has ignored several statements, and the secretary suggests that "we would like you to pay something on your account," the patient replies that "the doctor said I didn't have to worry about it." Or, in instances of major surgery of which we have known, the "reasonable" charge the physician brushed away in advance turns out to be the equivalent of three or four months' wages for the patient's family! Local medical society grievance committees are more than slightly familiar with such situations. When the secretary or bookkeeper is receiving blame for laxity in getting out statements, we often find that the physician has the annoying and disrupting habit of deferring charges beyond any reasonable bounds. He may see a patient from three to six times during the month in the course of extensive diagnostic work and continue to postpone the assignment of charges for one or another reason. When he is finally cornered into setting his fees for all the various services performed, his office then bills them, sometimes two or more months after the services were performed, and he cannot understand why the patient exhibits a similar degree of neglect in meeting the bill.

IS THE SYSTEM TO BLAME?

When one or another method of collection program is attempted, the physician's most frequent error is to choose a system that is commercial in its approach and tone and impersonal in its application. Having bought the stickers to paste on statements or the series of "canned" printed form letters to be sent out, he will either expect them to operate automatically, which they will not, or will engage in a flurry of collection action for a month or two, then forget about the system entirely until the next time he finds his receipts have dropped off. We will have more to say hereafter about the various types of collection approach but for the moment will merely point out that whatever their merits, none of them can operate effectively unless they are applied regularly and intelligently and without playing favorites.

IS THE COLLECTION AGENCY TO BLAME?

When accounts are turned over for collection, we hear the agency abused, often in the same breath, for being too tough and for not getting the money. When the physician suddenly

Partners, Porterfield-Marks, Management Counsel, Affiliates of Black & Skaggs Associates, Inc.

decides to "clean house" and turns in a long list of accounts there will often be many who have received not more than three or four statements and no warning from the office that the bill was considered delinquent. Hence the first contact by the collector can come as a severe shock, no matter how gently it is phrased, and the patient may storm into the physician's office bursting with righteous indignation. Cornered, unwilling, and seemingly unable to admit the impulsiveness that prompted him arbitrarily to turn the account over, physicians have even said, "The agency had no business to threaten you this way. They came into my office and took your account without my knowing it," or something to similar effect. Such a physician does not back up the collection medium that he has selected and authorized, and his shifting of the blame, rather than improving the situation, merely results in the patient concluding that his office must be an extremely poorly administered one. On the other hand, he frequently threatens collector action and does not follow through with it. The patient then concludes that his bark lacks bite and promptly relaxes again. When, after months have elapsed, he carries out his threat, without further warning, the patient is rudely jolted, feels cheated, and becomes just as indignant. Perhaps by the time action is taken, it is found that the name or address or both are incorrect or inadequate; when the patient has moved without leaving a forwarding address, the doctor's records usually are lacking the business address, the referrer's full name and correct address, or any other subsidiary data and clues that might aid in locating him. Small wonder that, even with the credit association and other tracing facilities at the collection agency's command, so high a percentage of accounts must be reported as untraceable. Yet the physician will blame the collector for his inability to make up for the carelessness and slipshod recording of data, which began with the doctor himself.

IS THE PATIENT TO BLAME?

Finally, the doctor blames the ungrateful patient. So far we have been discussing the physician's administrative shortcomings; now we must consider a much more critical phase of his relations with patients. In fact, to jump from the specific topic of this paper to the sweepingly general, we can do no less than to state our strong belief that in his interpersonal relations with his patients lie the causes of the physician's success or failure in every aspect of his practice. While breakdowns in these relationships may occur in various other areas, they are currently most prevalent in the economic sphere, to the extent that they have generated a rather vicious type of class warfare between members of the healing professions on the one hand and the general public on the other. This antagonism may well go far deeper than the economic level, at which it is most apparent in our civilization. In most cultures and societies that the social anthropologists have been able to study, the status of the "medicine man" is a special one within the group. Whether he doubles as priest, shaman, or diviner, he is set apart from the remainder of the people. He deals with mysteries forbidden all others and holds the power of life and death over them. He is therefore both feared and honored, trusted and hated. He lives by tribute levied upon all, and when he fails, he is violently cast out. In our complex civilization, it is difficult to recognize or state the physician-patient relationship in these basic terms that still apply in primitive cultures, yet until fairly recent times it bore a strong resemblance to them. The apparent change arrived with the Industrial Revolution, which made financial return our primary measure of success and changed the physician's status from that of a largely subsidized practitioner to that of an independent businessman or entrepreneur. He held to his traditional code of ethics, which requires that he give freely of his art and skill to all who need and seek his services; at the same time he was forced to accept new economic obligations, which demand that he receive for those services a fee that will permit him to buy the goods and services he himself needs.

The physician thus finds himself in an anomalous position as he strives to fulfill his two conflicting goals. When he does not recognize the contradiction, he permits it to control his actions and attitudes on the emotional level and thus to warp

and distort his relations with his patients. This can hardly fail to provide a focal point for the later resentment or antagonism that is latent in the attitude of patients toward his profession and that will be encouraged by every sign of the physician's anxiety or uncertainty. While this conflict is probably inherent in our present culture, the physician who recognizes it can, to a large extent, redirect it so far as his own practice is concerned; in fact, he can use it to his own advantage. Our culture demands that each person "sell" his services in order to live, but the physician does not go into the market place and offer his services; instead persons seek him out to obtain them, usually with little thought beyond the immediate urgency of their need. While they know there will be expense and are concerned about the cost, this concern at first merely contributes to their anxiety whether the physician of their choice can and will cure them. From the beginning then, the physician must direct his efforts to relieving the general anxiety and in the process convert its various aspects, including the financial, into a reasonable understanding. He can never entirely succeed in placing their relationship on a completely objective and logical basis; indeed he should not attempt to, since his best success will be measured by his ability to mobilize the emotional factors in his favor, thus overriding the negative impact of the economic exchange upon both the patient and himself.

THE AVOIDANCE OF BLAME

With the new patient, the effort should be made to guide the relationship through the following phases: 1. The physician expresses immediate interest in the complaint, its cause, and history, giving assurance that he will take action against it as quickly as possible, but reminding the patient that for safety's sake he must learn the best methods to use for him as an individual. The emphasis on the best choice of action is essential to gain attention and get away from the hope for a "magic cure," while the stress on the person flatters the recipient that he is receiving attention from someone who considers him important and whom he should therefore like. 2. Advances in medical diagnosis and therapeutics then furnish examples further stressing the need for thoroughness and special attention to each person's problems, so that the patient will expect the physician to be equally thorough in treating him, will want him to perform whatever examination and tests are necessary, and will then freely divulge his previous medical history as an aid to that end. The patient's faith in tests and drugs as such must be converted into faith in the physician's judgment in interpreting and selecting them. His need for assurance that the physician is sympathetic is satisfied when he is encouraged to talk freely about his problems and himself. 3. The doctor can now outline the specific examination and diagnostic program for the patient with a good chance that it will be understood logically and accepted emotionally on a level of mutual trust rather than of fear. He can now and should tell the patient what the examination will cost and how it may be paid, as a means of alleviating the financial concern over the immediate service, and as a token that he will tell the patient beforehand what his future charges will be. Having brought the relationship from a potentially dangerous level of anxiety to a fairly rational basis, the physician flatters the patient as a practical person by introducing the economic aspect that earlier would have been embarrassing to both of them; in doing so he attacks the basis of resentment against the profession that "doctors are too high-and-mighty to talk about money but watch them grab for it!" Having established a principle at his initial meeting with the patient, the doctor will find himself obligated, and therefore it will be easier for him, to present in advance of its performance the fee for therapy and to make arrangements for the meeting of it.

While the above approach is directed primarily to the new patient who is seen not in intense pain, it can readily be applied to former patients or to new emergency patients as the acute phase diminishes. It is based on the need to demonstrate to the patient that the physician's first interest is in him as a person and on the recognition that their relationship begins as an emotional one. Reason and logic play but a small

part, unless a deliberate, well-planned, and sustained effort is made by the physician to guide both patient and himself from their first emotional reaction toward a reasoning understanding of the problem that they must solve together. While we cannot overlook the economic problem, we must recognize that no logical solution to it is possible while other aspects remain on the emotional level. Thus, when the physician accuses the nonpaying patient of ingratitude, he admits his failure in creating a sound logic-based relationship with that patient and admits that he has not been able to rise above the reactive level.

PLANNING THE COLLECTION PROGRAM

Returning to the practical aspects of collecting in the office, the first goal is to reduce the large backlog of outstanding accounts to the reasonable level of two to three months' charges. Here is often found the specious reasoning that a large amount of outstanding accounts is a safety factor and helps assure continuing income should the physician have to close the office for any length of time. We have already discovered, from a previous study, to what small extent such long-overdue accounts can be counted on in emergency or even when an active collection program is initiated in the continuing practice. As a practical rule of thumb, accounts with over six months' charges outstanding are only about 25% collectable, and those over a year old are essentially worthless.

To be effective, any program must be realistic. When an account carrying a large balance is known to be beyond the ability of the patient to pay, even in small installments, the old balance should be written off entirely or at least reduced to whatever amount the patient is capable of meeting. Cancellations should not be the result of guesswork or as part of a "general amnesty" but must each be discussed with the patient if possible to establish what is most fair. Whatever action is then taken must be accompanied by a clear understanding that future services will not be permitted to go unpaid to a like extent, the physician undertaking to present his reasonable charges as they are incurred and the patient to meet them at that time.

The so-called friends or similarly privileged patients who, we are frequently told, "are sure pay, when they get around to it," must be brought around to realize that their financial responsibilities are just as great as anyone's else. If this is not done, the physician will too often find that the money he has, in effect, loaned his friends will not be paid back, and the debt may even turn the friends into enemies.

The program must be moderate. We have seen that the sudden threat or brusque summons, after a long period of inactivity, may produce a violent reaction when the patient has become accustomed to an easy-going attitude. Therefore, initial contacts, whether in person or by letter, must be mild and friendly. When regular statements have produced no response, dunning notes on further statements are ineffective and are received as a gratuitous insult. Stickers attached to statements are even worse, particularly would-be humorous ones (why an overdue doctor's bill seems a subject for humor is something we have never been able to fathom). The "canned" printed credit reference type of form letter, with the patient's name obviously filled in later, is equally objectionable; all these collection methods are blatantly mechanical, routine, and commercial in their approach. While they may have some success in collecting money, they further break down any remaining vestiges of personal contact and friendly relationship between the office and the patient. Personal discussion in adequate privacy, at the office or by phone, is the most satisfactory contact method. Where such contact is not possible, individually prepared letters are the next best, with their major emphasis toward restoring that direct contact so that the payment problem may be worked out under the most favorable circumstances.

Only after a number of appeals have been ignored or promises of payment broken is the final threat to call in a collection agency justified; and this should be phrased "more in sorrow than in anger." When the final warning has been given without response, the account must be turned over for collection

action, or the success of the entire program is jeopardized. In numerous instances, we have seen every possible type of appeal ignored because this final step was not taken; when the doctors finally brought themselves to back up their threat with action, payments began to come in from patients who had imposed on them for years.

The selection of the proper collection agency is also of importance. The commercial agency customarily is geared to the type of approach in which final action is the repossession of merchandise and against accounts where retail credit rating is involved. Obviously, no medical services can be taken back for nonpayment; and we have observed that credit ratings seldom bear much relationship to financial delinquency in the doctor's office. The best choice of agency is the independent professional bureau which subscribes to the code of ethics of the National Association of Medical-Dental Bureaus, a leading organization of specialists in this field. Incidentally, while the national average of collections on medical accounts through general bureaus is around 30%, the better specialized bureaus report better than 50% and, for their clients who have set up good collection procedures within their own offices, one bureau reports 73% collections in a recent study. Once the collection agency has been selected on the basis of these criteria, it is essential that it be given adequate authority to take whatever action necessary. Strangely enough, this may often be the recommendation that the account be canceled entirely because of financial hardship.

The program must be persistent. All outstanding accounts must be reviewed each month as statements are prepared or at a convenient regularly scheduled time. Where two or three statements have brought no response or a promised payment has not been made, the account will be designated either for personal contact by the physician or secretary or for a letter suitable to the circumstances. Appropriately more severe contacts (usually by letter) will be prepared and sent to patients who have ignored the previous month's letter. Those who have ignored the final appeal or who have disappeared leaving no address will be listed with all available information for assignment to the collection bureau. There is a wide difference of opinion as to how many months of letters should be planned before the final action. In a well-established program, we favor a maximum of around six months where the account has not previously been delinquent. Where previous contact has not proved entirely effective or in a new program with a heavy backlog of long overdue accounts, an accelerated campaign may be necessary. No set rule can be stated, since each account must be considered individually and the action suited to the circumstances.

MANAGING THE COLLECTION PROGRAM

An effective program requires time and effort to plan and to maintain. The physician himself carries the greatest responsibility and in his attitude toward his financial relations with patients and the prevention of future delinquency lies the key to the correction of that already built up. Much of the burden of actually administering the program can, however, be taken from his shoulders by his staff or by management counsel serving as auxiliary staff. In fact, such an objective viewpoint and experience in preparing collection letters has been one of the most important advantages to the clients of such services whose role in collections must remain that of the doctor's anonymous secretary. However the program is administered, the cost and effort will pay good dividends to the practice. Better collections are the directly measurable result and certainly an important one. Better relations with patients will also result, and these may take the form of a healthy growth of the practice or of improving the general level of patient cooperation. These better relations will play an important part in avoiding the ill will that otherwise may lead to complaints before the society's grievance committee or to a malpractice suit. The continuing studies of grievance cases and court actions against physicians confirm that around 90% of them originate with unpaid bills, so, in this respect as well, it pays to do your own collecting.

Thymus Problem.—A review of the thymus problem was undertaken three years ago at the Guthrie Clinic and Robert Packer Hospital. Approximately 2,600 infants and children have been studied in an attempt to obtain answers to the following questions. What is the normal anatomy of the infant mediastinum when shown in roentgenograms? Can obstructive symptoms be caused by the thymus? How often is respiratory stridor due to tracheal compression by the thymus? When is radiation therapy indicated? The results obtained largely coincide with those of earlier studies in which little concrete evidence was found to support a connection between the thymus gland and symptoms of stridor, cough, and cyanosis or sudden death. Roentgenographic appearances formerly believed to represent abnormalities of the thymus are now known to be characteristic of the normal anatomy and physiology of the infant mediastinum. Tracheal compression has never been satisfactorily demonstrated by roentgenographic means, and efforts to detect it on fluoroscopic examination of normal infants during extremes of flexion and extension of the head failed to show sufficient narrowing of the trachea to produce respiratory embarrassment. Stridor and other symptoms supposedly due to an enlarged thymus may in reality be caused by congenital conditions or disorders such as atelectasis, tracheal or laryngeal stenosis, whooping cough, or meningitis. Hundreds of babies are undoubtedly receiving unnecessary radiation therapy because of widened mediastinal shadows. Children subject to repeated bouts of stridor, cough, and cyanosis, however, are benefited, often dramatically, by radiation therapy, probably because they have an underlying low grade, chronic, or recurrent tracheobronchitis that is favorably affected by the treatment.

Periodicals on file in the Library of the American Medical Association may be borrowed by members of the Association or its student organization and by individual subscribers, provided they reside in continental United States or Canada. Requests for periodicals should be addressed "Library, American Medical Association." Periodical files cover only the last 11 years, and no photoduplication services are available. No charge is made to members, but the fee for other borrowers is 15 cents in stamps for each item. Only three periodicals may be borrowed at one time, and they must not be kept longer than five days. Periodicals published by the American Medical Association are not available for lending but can be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them.

Titles marked with an asterisk (*) are abstracted.

Postprandial Hypolipemia of Pancreatic Fibrocystic Disease.—Pediatricians need to distinguish between fibrocystic disease or fibrosis of the pancreas and other disorders of nutrition clinically diagnosed as celiac disease. The symptoms of patients with fibrocystic disease are comparable to those observed in dogs after ligation of the pancreatic duct and can be ascribed to the absence of the external secretion of the pancreas. Fat foods are not tolerated, and the deficiency of pancreatic enzymatic activity results in a marked lack of fat absorption from the bowel. Studies of the esterified fatty acid content of the blood during the postprandial hyperlipemia of normal adults and of diabetics suggested that it could be used as a measure of pancreatic function in children in whom fibrocystic disease was either present or suspected. The esterified fatty acids of the blood at the so-called fasting level in normal children aged 8 weeks to 7 months were found to range between 7.2 and 13.8 mEq. per liter. The postprandial increase following a test meal of 36% cream in an amount calculated to give 4 gm. of fat per kilogram of body weight ranged to as much as 31.7 mEq. per liter. Children with fibrocystic disease, in whom pancreatic function is markedly decreased, show only a slight rise or none at all in the esterified fatty acid content of the blood after a similar test meal. Estimation of the esterified fatty acids at the fasting and the four and six hour postprandial levels in children given this test meal by mouth therefore constitutes a convenient laboratory method of evaluating pancreatic function.

Isoniazid in Skin Diseases.—Isoniazid (Nydrazid) was given to 9 patients with tuberculosis of the skin, to 15 with tuberculid, to 8 with leprosy, to 4 with sarcoid, and to 14 with miscellaneous conditions. The drug had a decidedly beneficial effect in all nine cases of lupus vulgaris and scrofuloderma. The response of tuberculid to therapy was poor in 11 cases, excellent in 3, and satisfactory in 1. In three cases of lepromatous and one of indeterminate leprosy, the disease responded satisfactorily after three to four months of continuous therapy. There was no response to isoniazid in three cases of tuberculoid leprosy. The drug was not of benefit in four cases of sarcoid, three of dermatitis herpetiformis (Dühring's disease), 7 of chronic discoid, and one of chronic disseminated lupus erythematosus. Doses of 0.2 to 0.6 gm. daily were well tolerated. Reactions were somewhat troublesome when daily doses of 0.8 to 1.2 gm. were given, but there was not a single severe toxic reaction. There was no definite evidence that daily doses of 0.8 to 1.2 gm. of isoniazid were superior to the smaller doses.

Inhalation Toxicity of Beryllium.—Acute beryllium poisoning by inhalation was studied in a variety of animal species exposed to beryllium fluoride mist in a closed chamber. Two experiments were performed; in the first, exploratory in nature and of relatively short duration, 6 dogs, 6 cats, 20 guinea pigs, 20 female albino mice, 10 male rabbits, and 40 albino rats were exposed daily to concentrations of 10 mg. of beryllium fluoride per cubic meter. In the second and definite experiment, 14 dogs, 5 cats, 10 male rabbits, and 120 male albino rats were exposed daily to concentrations of 1 mg. of beryllium fluoride per cubic meter. In all species, lesions attributable to the effects of inhaled beryllium fluoride were confined to the lungs. These pulmonary lesions resembled closely the lung changes resulting from inhalation of beryllium sulfate. Beryllium fluoride is acutely more toxic than beryllium sulfate. Exposure to 1 mg. per cubic meter of beryllium fluoride (190 mcg. of beryllium per cubic meter) resulted in lung damage in cats, dogs, rabbits, and rats roughly comparable in extent and degree to that produced by 10 mg. of beryllium sulfate hexahydrate per cubic meter (420 mcg. of beryllium per cubic meter). The severest and most extensive lesions occurred in the lungs of dogs, while the changes were minimal in rats and intermediate in cats and rabbits. Hematological changes suggestive of the progressive development of macrocytic anemia occurred in dogs and rabbits during exposure to 1 mg. of beryllium fluoride per cubic meter. The anemia was severer than that observed after inhalation of beryllium oxide dust or beryllium sulfate mist. Daily administration of a dietary supplement of a proprietary liver-stomach concentrate with iron and vitamin B complex (Lextron) failed to prevent the development of anemia in dogs, and vitamin B₁₂ alone in the dose regimen employed (9 to 12 mcg. in three and four doses at 48 and 72 hour intervals) proved of little prophylactic or therapeutic value. A feature of the anemia developing during exposure to beryllium fluoride was a decrease in the proportion of mature polymorphonuclear leukocytes in the circulating blood and a concomitant increase of immature forms. Urinary uric acid excretion appeared to hold promise as an index of the degree of exposure to beryllium. Beryllium tended to accumulate in the lungs, pulmonary lymph nodes, liver, skeleton, and bone marrow of dogs. The rate of deposition in the lungs and the pulmonary lymph nodes increased with the duration of exposure. The data obtained by spectrophotographic analysis of tissues for beryllium suggest that there are specific differences in the rate and possibly also in the manner in which inhaled beryllium fluoride is mobilized from the primary site of deposition in the lungs and distributed to other tissues or excreted in the urine and feces in cats, dogs, rabbits, and rats. In relation to the quantity of beryllium in the lungs, a considerably greater portion was distributed

to the skeleton, liver, spleen, and kidneys of dogs after inhalation of beryllium fluoride than was observed in previous studies of the insoluble beryllium oxide or the soluble and readily dissociated beryllium sulfate mist.

The Allergic Load.—Increasing numbers of otolaryngologists have incorporated into their practices the treatment of allergic diseases of the ears, nose, and throat, but some have become dissatisfied with their results. One important reason for this was a failure to consider the patient as a whole. Another major cause may be that, in their preoccupation with the antigen-antibody relationship, they failed to consider other factors that may greatly influence the allergic reaction. The authors are concerned with the concept of the allergic load, which may be defined as the sum total of the contributory or exciting factors that play a part in the production or modification of allergic symptoms. The contributory factors do not produce an allergic attack themselves, but affect the person in such a way as to precipitate or aggravate allergic reactions. The specific, or exciting, factors are the antigens or allergens. The allergic load may be increased as a result of either massive exposure to a single antigen or simultaneous exposure to a number of substances, most allergic persons being sensitive to more than one substance. The authors comment on therapeutic measures that are directed toward reducing the load, such as making the dust-sensitive person's home dust-free. They also discuss subclinical allergy, which means a state of sensitivity to one or more substances that do not produce symptoms except under certain conditions of massive exposure or concomitant exposure with other allergens or when the symptom threshold is lowered by some contributory factor. Common conditions which the authors have found to increase the allergic load are smoking, anemia, hypercholesterolemia, sex hormone influences, particularly in women (menstruation and menopause); hypothyroidism, and psychosomatic influences.

Cancer of Colon and Rectum in a General Hospital.—Of the 171,171 cancer deaths that occurred in the United States in 1941, 29,000 were caused by cancer of the bowel. In an effort to clarify some of the problems presented by this type of cancer, Kratzer reviewed the 197 cases of cancer of the colon and rectum observed at the Allentown General Hospital during the three year period from 1947 to 1949 inclusive. Surgical treatment was employed in 165 of these patients; that is, the operability rate was 83.7%. Of the 165 patients operated on, 40 had exploration only or a simple palliative procedure and 125 had resection. Of the patients in whom resection was performed, 58 were subjected to the Miles' one stage re-

section, 27 to a multiple stage procedure, 36 to resection with primary anastomosis, and 4 to the pull-through type of operation. Evidence of spread beyond the bowel wall was noted in 42 patients. There were 10 operative deaths. Five were attributed to cardiac disease, two to pulmonary embolism, one each to peritonitis, postoperative shock, and phlebitis. Thirty-two patients survived over four years. This survival rate of 28% is discouraging. It is believed to be due to delay on the part of the patient in seeking advice. The cases of the patients undergoing extirpation of the rectum in 1947 were reviewed in an effort to determine the five year survival rate. Six of these 18 are alive today. The patients operated on in 1948 had a four year survival rate of 43%. It is probable that this increase in survival rate will continue from year to year. A modification of the two stage abdominoperineal resection as performed on one of the services for certain cancers situated in the lower portion of the rectum at the Allentown Hospital is described.

Nongonococcal Urethritis.—Forty-five Navy men with a urethral discharge in which the gonococcus could not be found by smear or culture were thoroughly studied concerning the etiology and epidemiology of their urethritis. For each patient admitted to the Navy hospital for study and treatment, a hospital corpsman with a history not including recent febrile illness or any genitourinary tract disease was selected for study as a paired control. The history obtained from the 45 patients revealed a characteristic story of mild, lower urinary tract inflammation with only minor variations in degree. All of the patients had had intercourse within a period of 55 days of the onset of urethritis. The average period of time between intercourse and the onset of urethritis was 15.2 days, and urethritis developed within 10 days of exposure in 25 patients. The cytological picture of the urethral discharge was that of two distinct exudates. One consisted primarily of polymorphonuclear leukocytes associated with rare eosinophils and epithelial cells. The other type was primarily made up of epithelial elements. The cytological picture of the prostatic secretion was one of predominant leukocytes with rare cuboidal epithelial cells, small lymphocytes, plasma cells, macrophages, and eosinophils. The flora of the lower genitourinary tract was varied in character and abundant. Gram-negative bacilli, corynebacteria, gram-positive bacilli, gram-positive cocci and fungi were cultivated from the urethra, urine, or prostate in all patients before and after therapy with oxytetracycline (Terramycin). (Neisseria were isolated in only two patients and were proved not to be Neisseria gonorrhoeae.) With this therapy the urethral discharge, containing predominantly morphonuclear leukocytes in 35 patients, changed strikingly to an epithelial exudate. All 41 patients treated with oxytetracycline noted a rapid decrease in amount and change in character of the discharge. The irritative symptoms promptly disappeared and so did the pyuria. Thirty-seven patients were free of urethral discharge within seven days after the institution of therapy. Transient recurrences of mucoid discharge occurred

20 times in 14 patients after their release from the hospital. All recurrences were epithelioid in character. The species of bacteria present in the control group were quantitatively and qualitatively similar to those of the patients. The impressions gained from this study are as follows: nongonococcal urethritis is a disease of sexually active persons, but it was not proved to be venereal in origin and should not be so classified. The clinical picture is one of a mild inflammatory disease of the lower genitourinary system and is not confined to the anterior urethra. "Abacterial" urethral exudates do not exist. A specific causative agent was not found, and further investigation must include that of the existing flora of the urethra and its accessory apparatus. Known forms of the gonococcus play no causative role in this disease. The associated prostatic inflammation is probably the most important component of this syndrome. Oxytetracycline is the most effective form of therapy available.

Treatment of Interstitial Keratitis.—Of 35 patients with interstitial keratitis resulting from congenital syphilis, 10 were treated with penicillin alone, 14 with penicillin combined with fever therapy, and 11 with penicillin, fever therapy, and topical cortisone (Cortone). Results showed that there is no drug with a specific effect on interstitial keratitis. Penicillin failed to affect the course of the disease in any way. Fever therapy had some influence on both subjective and objective symptoms of interstitial keratitis. The ultimate place of cortisone and corticotropin in the treatment of interstitial keratitis is still undetermined. Although hormone therapy frequently results in a rapid and pronounced change in the course of the disease, this change is, as a rule, of a transient nature. Possibly the hormones, in so far as they bring about a most lasting improvement in the early phase of the disease, cause a return to the previous condition, and the predisposition of the cornea to the disease remains equally high.

Carcinoma of Stomach.—The results of treatment of 158 patients with carcinoma of the stomach admitted to a general hospital, the New Haven Hospital, for definitive treatment in the years 1941 to 1946 were compared with the results in two previous periods, 1920 to 1930 and 1931 to 1940. There has been a significant increase in the ratio of five year survivals to total admissions in each series. This increase is undoubtedly due to an extension of indication for gastric resection and an increase of the number of resections at the expense of palliative

procedures such as gastrostomy and gastroenterostomy with a simultaneous decrease in mortality. At the present time, there are 17 patients living more than five years without evidence of recurrence of the total of 486 (3.5%) diagnosed between 1920 and 1946. Eight of these have survived more than 10 years. This is not a negligible number of long survivors and deserves consideration by those who call this a hopeless lesion. Unfortunately there has been no significant decrease in the ratio of inoperable lesions in patients admitted and no significant change in delay before referral of patients for definitive treatment. The greatest hope for a really satisfactory cure rate of carcinoma of the stomach would seem to be an adequate screening test for cancer. Earlier diagnosis by an increase in the index of suspicion by physicians and patients is the only apparent means at present available. Extension of surgery as by more radical or total gastrectomy possibly will give some further improvement if the surgical mortality rate can be decreased at the same time and adequate methods of replacement therapy are developed.

Cancer of Uterine Cervix.—Carcinoma in situ means cancer in its normal or original location. The lesion has been defined as "a condition in which malignant epithelial cells and their progeny are found in or near positions occupied by their ancestors before the ancestors underwent malignant transformation." Such changes may exist in any site in which cancer arises and, in the female genital tract, have been observed in the uterine tube, endometrium, vulva, vagina, and uterine cervix. This study was made to acquire a detailed knowledge of in situ cancer so that comparison with squamous cell cancer would be possible and additional evidence suggesting relationship might be obtained. During a five year period histopathological examinations were made on 5,044 cervixes, including 126 amputated cervixes, 2,543 complete uteri, and 2,375 cervical biopsies. The latter included sharp or cold knife conizations, wedge resections, and multiple punch biopsies. Of the 5,044 patients represented, 3,643 were white, 1,395 were Negro, and 6 were members of the yellow race. The mean age at the time of examination was 45.4 years in the white and 37.2 years in the nonwhite group. Carcinoma in situ was found in 100 of the 5,044 cervixes (about 2%). During the same five year period, 225 cases of squamous cell carcinoma were observed. In comparing these two groups of patients, it was found that in both in situ and squamous cell cancer: (1) the average age at detection was less in the Negro than in the white patient; (2) the occurrence was more frequent in the Negro than in the white woman; (3) the lesions were less common in Jewish women than in those of other religions; (4) a relatively high proportion of the patients were parous; (5) the component cells were identical; and (6) the anatomic distribution was similar. In some 10,000 women subjected to cellular examinations, the prevalence of in situ cancer was 41 cases as compared with an expected prevalence of 34 to 43 cases under the assumed conditions. The criteria used in recognizing in situ cancer are described, and the differentiation from atypical hyperplasia and squamous cell cancer is considered.

Role of Follicular Fluid in Fertility.—According to Kurzrok and associates, data are meager concerning the progress of spermatozoa in the human female genital tract toward the ovum and the progress of the ovum from the ovary into and

through the tube toward the spermatozoa. They feel that human follicular fluid plays a greater role in fertilization than has been supposed, and they review considerations that tend to indicate this, such as that fertilization is limited by a time factor, that spermatozoa behave somewhat like cilia, and that the differing diameters of the various parts of the fallopian tubes influence the energy imparted to the follicular fluid. Experiments are described that show that human follicular fluid serves as a nutrient medium for human spermatozoa. Spermatozoa survive longer in follicular fluid than in seminal plasma. Similarly, the intensity of motility is supported. The nature of the substance in follicular fluid producing this effect is still unknown. It is hoped that further studies of human follicular fluid will yield additional information that will be helpful in the therapy of infertility. The authors suggest the theory that follicular fluid is involved in the progress of ovum and spermatozoa toward one another within the female genital tract and that fertilization occurs within this fluid. Follicular fluid flows from the peritoneal cavity through the tubes and out through the tubal ostium into the uterus where it is channeled toward the cervix. Spermatozoa move only in a fluid medium, hence pass into the tubes by swimming in these fluid channels from the cervical canal toward and through the tubal ostium. The passage of spermatozoa into the tubes is, therefore, a directed phenomenon and not a fortuitous occurrence. The clinical significance of these findings is discussed.

Esophageal Varices in Cirrhosis of the Liver.—Of 150 patients with microscopically confirmed cirrhosis in whom esophagoscopy was done as a routine procedure, 59 had a history of hemorrhage and 91 did not. Varices of the esophagus were diagnosed in 95 (63.3%), 47 of whom had a history of hemorrhage, while 48 (52.7%) did not. A fairly high incidence of varices thus occurred in cirrhotic patients who had no history of hemorrhages. No untoward effects of the endoscopy were observed in the 150 patients. In addition x-ray studies with specific instruction to the radiologist to search for esophageal varices were done in 147 patients, in 92 (62.5%) of whom varices of the esophagus had been demonstrated esophagoscopically. In 19 (12.9% of the 147 and 20.6% of the 92) the roentgen diagnosis was positive for esophageal varices, and 15 of these 19 patients had a history of bleeding. The comparative diagnostic value of x-ray study in this series thus indicated that only 21% of the cases of varices present were diagnosed by that method. Esophagoscopy enabled diagnosis of a larger number of cases of esophageal varices than could have been afforded by any other method. In view of the high incidence of esophageal varices in patients with cirrhosis, even without a history of bleeding, routine esophagoscopy, which had been shown to be a safe procedure, should be done in every patient with cirrhosis.

Spontaneous Rupture of the Esophagus.—The occurrence of spontaneous rupture of the esophagus is reported in a 51-year-old woman who complained of weakness, dyspnea, generalized abdominal discomfort, and retrosternal pain of six to eight hours' duration after an episode of violent retching and hematemesis. A shock-like condition developed, and a left hydropneumothorax was observed on physical examination. Aspiration of the left pleural cavity yielded 1,200 cc. of sanguinopurulent fluid that on Gram staining revealed many gram-positive and gram-negative cocci and bacilli, some of which had the morphological appearance of clostridia. The patient vomited once after admission; the vomitus consisted of 200 cc. of dark green fluid with a fecal odor. She denied dysphagia and drank as much as 250 cc. of water without distress. Her temperature rose to 103 F (39.5 C), and respirations and pulse were rapid. Rupture of the esophagus was considered but not seriously entertained until about one hour before her death because of absence of symptoms referable to the esophagus, normal esophageal function tests, and continued vomiting. Death occurred in the 19th hospital hour during the course of a diagnostic work-up. Necropsy revealed a longitudinal tear measuring 2 cm. in the left lateral wall of the esophagus through which a probe could be passed through the adjacent mediastinal tissue into the left pleural cavity. It is imperative to consider spontaneous rupture of the esophagus in patients with severe epigastric or precordial pain that occurs during violent vomiting or retching. Pneumothorax and subcutaneous emphysema may be observed frequently on physical examination. Although the diagnosis is established only by demonstration of a communication between the esophagus and pleural cavity, strong confirmation is obtained when hydrochloric acid, vegetable material, and/or clostridia are found in the pleural aspirant. Extensive perforation may be present without dysphagia.

New Anticholinergic Drug, Pro-Banthine.—A new isopropyl analogue of methantheline, propantheline (Pro-Banthine) bromide, was given a therapeutic trial in 156 patients with various gastrointestinal disorders. The most striking effect of this new anticholinergic agent was the relief of pain in peptic ulcer and the inhibition of motility in patients with diarrhea, especially of the functional type. In this regard it mimics the action of methantheline (Banthine). The relief of pain, when achieved, was prompt and usually complete. Most patients were relieved of pain within 48 to 72 hours after doses of 30 to 45 mg. of the drug four times daily were instituted. Of the 156 patients, 129 had active peptic ulcer, and 106 of these were completely relieved of pain, 12 were significantly relieved, and 11 were considered failures because they could not tolerate the drug or were not relieved of their symptoms. Clinical impression, supported by roentgen studies, was that there is definite acceleration of healing of the ulcer crater while under treatment with propantheline. Patients with severe manifestations should receive 30 to 45 mg. of the drug every six hours. After two or more weeks, a maintenance dose of 15 mg. four times daily may be used. Initial dosage of 15 mg. four times daily may be given to patients with less severe manifestations. Recurrences of ulcer symptoms while on maintenance dosage were relieved by raising the dose to therapeutic levels. Six patients with functional diarrhea were either completely or significantly relieved of their symptoms. Propantheline proved useful in the control of postoperative regional ileitis and the symptoms of the dumping syndrome. It was of less value in treating ulcerative colitis. The usual side-effects noted with methantheline were also observed with propantheline but to a much lesser degree. The previously unreported side-effects of urinary frequency and headache were noted, although these were rarely sufficiently severe to require discontinuation of the drug.

Trauma and Cardiac Complications.—Lajoie points out that there remain two schools of thought on trauma as a cause of cardiac complications. One believes that "the heart lying against the sternum is vulnerable to compression forces applied to the chest." This is especially true in children in whom the chest cage is easily compressed. The other school claims that "the heart is a compact, spindle mass of continuously moving muscle that lies in a soft, yielding bed, is well protected by bones, and cannot be reached by a crushing violence, unless the force is exceptionally severe." Judging from recent medical literature, it seems that the first school of thought is the more popular. Two of the most important nonpenetrating injuries of the heart are discussed and illustrated by case histories. The first is injury to the muscle or contusion of the heart, which occurs in what is referred to as the steering wheel injury. Electrocardiographic studies should be made whenever there is a history of injury to the chest particularly in automobile accidents. The second nonpenetrating injury of the heart is acute coronary occlusion with myocardial infarction that occurs in the course of employment. In this connection the author cites the case of a truck driver, aged 41. While he was rolling lumber off a truck and using a crowbar to pry the rollers, the bar slipped from his hand and he struck his chest against the roller. He immediately experienced pain across his chest, and his breath was shut off for a few seconds. He rested for a few minutes, but when he resumed his work the pain in his chest was severe. He perspired profusely and had difficulty in breathing. On the fourth day the pain became so severe that he consulted a physician who examined him and told him that he had had a heart attack. This was confirmed by electrocardiographic findings. The author observed this patient for more than a year and found a gradual electrocardiographic improvement, the tracings returning almost to normal, which is unusual in a person of his age group. He has now changed his opinion and concluded that the man had had contusion of the heart. The claim was accepted by the insurance carrier and compensation was paid. In dealing with an industrial cardiac problem, a detailed history should be obtained, and the report should be thoroughly studied before a final opinion is given. A claim is likely to be denied in the absence of stress, strain, or overexertion or when several hours or days elapse between the accident and the symptoms. When the worker is aware of symptoms during, or immediately after, unusual stress or strain, acceptance of a causal relationship between occupation and disability is justified.

Electrocardiographic Studies During and After Inhalation of 30% Carbon Dioxide.—The use of 30% carbon dioxide inhalation for treatment of a series of psychiatric patients gave MacDonald and Simonson an opportunity to study the resulting

electrocardiographic changes. The studies were made on 17 men who were psychiatric patients, who ranged in age from 25 to 48 years, and who had no history or signs of cardiac disease or hypertension. Chest roentgenograms and electrocardiograms were normal before treatment. A total of 27 treatments were studied electrocardiographically. Some disturbance of auricular or ventricular activity appeared in 12 of the 17 patients. Auricular changes were found in 11 patients; ventricular extrasystoles appeared in 5 patients, including one patient who exhibited a brief period of ventricular bigeminy. The P-wave changes found included low voltage and inversion. The following abnormalities of rhythm were noted: auricular and nodal premature beats, auricular tachycardia, supraventricular tachycardia, and an irregular supraventricular pattern of probable auricular ectopic origin. Increased T-wave voltage was seen during carbon dioxide inhalation in nine instances. The authors feel that, while the changes they observed are by no means alarming in themselves, their nature suggests that serious disturbances, supraventricular or ventricular, could occur. Their patients were relatively young, selected for the absence of evidence of heart disease; nevertheless, 12 of the 17 patients showed some abnormality. The possibility that heart disease, particularly latent coronary insufficiency, could contribute to the development of more serious disturbances is clear. Electrocardiographic observations are recommended during each treatment with 30% carbon dioxide in order to insure maximum safety.

Complications of Chronic Ulcerative Colitis.—Kleckner discusses the complications of chronic ulcerative colitis on the basis of observations on 425 cases. They should be treated promptly after careful study to determine whether they originate in the colon itself or from other systemic disturbances. Polyps, strictures, perforations, hemorrhages, and abscesses with fistulous formations and malignant change are the complications most frequently encountered. Other systemic disorders, such as cardiorenal changes, nutritional deficiencies, and arthritis, may occur in conjunction with chronic ulcerative colitis. They may develop independently of the colonic lesions or occur as a result of the general toxemia or lowered resistance associated with chronic ulcerative colitis. A very important factor in many cases is the lack of proper psychosomatic approach. The author regards it as unfortunate that patients are being told that "a colitis" (or oftener, "a spastic colitis") is present, although the only symptom is slight tenesmus or the passage of variable amounts of mucus in the stools. Rarely is proper proctologic study given. Complications occur in the infected areas mainly because of delay in treatment. The author further comments on some of the complications of chronic ulcerative colitis, particularly on the incidence of carcinoma in these patients. In his own series the incidence of carcinoma was 4%, but he is of the opinion that this is too low a percentage

to be accurate, because he was unable to follow up many of the patients for a sufficient length of time. Had he been able to follow all the patients carefully, he is convinced that malignant disease would be revealed in over 10%. He feels that 25 to 30% of patients with chronic ulcerative colitis require more than medical treatment, and that only ileostomy or colectomy will produce cure.

Hearing Loss in Drop Forge Workers.—During the years 1950 to 1952 Fox examined 64 drop forge workers who had filed claims for alleged loss of hearing resulting from their work. Otologic, audiometric, and ear, nose, and throat studies were made. Medical consultation was requested when indicated. One worker was malingering, and another had psychogenic deafness. The hearing losses in the other 62 workers were proportional to the length of employment. The ability to hear conversational voice, on the average, followed the audiometrically determined hearing losses. The diagnosis of industrial hearing loss was based on the record of employment in areas of intense noise, the medical history, and objective findings. Intense noise levels were present in the forge plants. There were no records pertaining to preemployment hearing, despite the fact that most of the employees had been given routine preemployment physical examinations. Therefore, it became necessary to rely on the applicants for the history pertaining to past hearing impairment or ear disease. Records from school or military service were obtained in a few instances. The extent of hearing impairment claimed by the workers varied considerably. Some had trouble only with high frequency sounds like the ring of the telephone and doorbell or the ticking of their watches. Others complained of being able to hear, but not clearly; while some had great difficulty in hearing any speech. The hearing of each worker was examined several times,

but this study cannot tell the complete story of this type of hearing loss. There is need for basic investigations in the forge plants. The hearing status of the worker will have to be studied at the time he begins employment, and it should be checked periodically. Functional relationships between the exposure factors and hearing loss will have to be determined as well as the effectiveness of methods used to reduce noise intensity. The medicolegal problems that confront the otologist indicate that the scientific bodies now investigating the various aspects of industrial hearing loss will have to revise and modify presently used formulas and methods of evaluating functional hearing.

Backache in Soldiers.—During the Korean war a large number of patients with the chief complaint of backache came from military units actively engaged in combat or from installations directly in support of these units. It soon became apparent that objective evidence of significant medical, orthopedic, or neurological disease was lacking in a large percentage of them. The symptoms and signs exhibited by many suggested that the backache was a symptom of psychiatric disease. The clinical records of 122 patients, representing consecutive cases, were reviewed, and each of these patients was seen by one or both of the authors. Although most of these patients were referred by physicians to Tokyo Army Hospital with the diagnosis of some form of local disease of the back, only 38.5% had significant, objective evidence of local back disease. In the 54.2% of the soldiers who had no objective evidence of local disease of the back, examination, history, and course of disease suggested that backache was a symptom of a neurosis—either hysteria or anxiety neurosis. A special group of 49 patients, which included some of the 122, were classified psychiatrically—69.4% of these patients were considered to have hysteria and 30.6% anxiety neurosis. The largest majority (83%) of the men with significant, objective evidence of local disease of the back were accounted for by the diagnosis of herniated nucleus pulposus, rheumatoid spondylitis, and acute back injury or strain. When no significant, objective evidence of local disease of the back was found, the patients were told just this. They were treated with reassurance and suggestion and were told that they must return to duty since no medical disability existed. Seventy-nine per cent of these were returned to duty.

Resection of Anginal Pathway for Relief of Anginal Pain.—

High thoracolumbar sympathectomy was performed in 16 patients with anginal pain, 14 of whom were hypertensive and 2 normotensive. The follow-up period for the series was from six months to three years. The anginal pathway is composed of sympathetic fibers passing through the inferior cervical fused with the first thoracic ganglion (stellate ganglion) and direct fibers from the cardiac plexus passing through the first, second, third, and fourth thoracic ganglia. The best results were obtained in patients who had complete resection of the anginal pathway bilaterally, but less extensive resection also proved satisfactory in many patients. The reduced danger accompanying limited resection makes it advisable for patients whose anginal syndrome is mild. Relief of pain was complete in five patients, complete except for a residual sense of throat constriction in four, and satisfactory in four. Residual throat or jaw pain was not a constant finding, and warning throat pain, when it occurred, appeared at a greatly increased exercise-tolerance level. The operation sometimes produces a Horner syndrome, but this need not be taken as a contraindication because the disadvantage it represents is far outweighed by the relief obtained and in addition the ptosis may become less pronounced in time. Resection of the anginal pathway should be confined to patients with severe angina associated with hypertension; normotensive patients with an "over-alarm" syndrome who have not recently suffered a coronary infarction may also be benefited, but the results in such patients will always be less satisfactory than those in patients with hypertension.

Fever as Sign of Quinidine Toxicity.—Two brothers with auricular fibrillation and thyroid hyperfunction were treated with quinidine, and in each drug sensitivity took the form of fever with temperatures of 104 and 105 F respectively. The only other toxic reaction was a mild diarrhea. The sensitization by previous doses, the discrepancy between the height of the fever and the patient's well-being, and the rapid decline in the temperature in from 24 to 48 hours after discontinuance of the drug, which have been mentioned by others as criteria for the diagnosis of fever due to quinidine, were all present in these patients. Each had a cryptic type of hyperthyroidism, and in each there was a relatively slow ventricular rate associated with auricular fibrillation of the coarse flutter type. Fibrillation persists in one patient who has been treated with propylthiouracil, procaine amide (Pronestyl) hydrochloride, and digitalis medication; in the other, who was also treated by surgical removal of cystic thyroid tissue, each of these drugs has proved effective in restoring the rhythm to normal (on three separate occasions). A sudden rise in the temperature of a patient with auricular fibrillation suggests embolism or bacterial endocarditis; when such a rise occurs in a patient receiving quinidine, use of the drug should be stopped before these diagnoses are considered, unless other overt signs of arterial obstruction or blood stream infection are present.

 *Induction of Pituitary Tumors by Means of Ionizing Irradiation. A. C. Upton and J. Furth.—p. 255.

Protective Effect of Cysteine Against Irradiation.—Control and experimental animals (mice) were irradiated simultaneously, caged together in groups of 10 to 15, and otherwise handled similarly. Cysteine was administered as a 12.5% solution of the hydrochloride neutralized to pH 7 with 10 N sodium hydroxide. Only freshly prepared solutions were employed. The cysteine dose was 1,200 mg. per kilogram of body weight and was given intravenously. Control mice were injected with an equivalent volume of 5% sodium chloride. In general, cysteine was injected between 5 and 15 minutes before exposure. The exposure time varied from 80 to 90 minutes for gamma rays and 60 to 90 minutes for neutrons. Pretreatment with cysteine was found to confer significant protection against the acute lethal effects of gamma Cobalt 60 (Co⁶⁰) and fast neutron (fission) irradiation in mice. The protection observed with fast neutrons is, however, about half of that found with gamma irradiation.

Effect of Heat on Agent of Homologous Serum Hepatitis.—The etiological agents of serum hepatitis and of infectious hepatitis are unusually resistant to chemical and physical methods of inactivation. The occurrence of numerous cases of homologous serum hepatitis following inoculation of certain lots of yellow fever vaccine to which human serum had been added demonstrated that the agent of homologous serum hepatitis can survive heating at 56 C for 30 to 60 minutes. The present study was part of an extensive program concerned with the safety of blood and blood products with respect to viral hepatitis. Material from a single large pool of infected plasma, referred to as infected pool plasma, was used in all the studies on the safety of plasma and its derivatives. It was found that samples of plasma known to contain the agent of homologous serum hepatitis retained their ability to produce hepatitis even after being heated at 60 C for 4 hours.

Induction of Pituitary Tumors by Ionizing Irradiation.—Large numbers of mice were exposed to atomic detonation. Some were not shielded and received predominantly gamma rays of high energy; some were shielded with lead to eliminate most of the gamma rays. The latter group is spoken of as neutron-exposed

animals. The mice remained in individual cages until natural death or were killed in extremis. Necropsy studies were done on all animals. A table recording the results indicates that 4 to 12% of the females exposed to from 192 to 733 r developed pituitary tumors as compared to 0.3% of the controls. No pituitary tumor occurred among the control males, while 2 to 5% of the males exposed to from 491 to 785 r developed such tumors. The dose acutely fatal to 50% of the animals was about 750 r. Pituitary tumors began to appear in larger numbers 16 months after irradiation, and they occurred with greatest frequency in the 23 to 25 months' postirradiation groups. In neutron-exposed mice it seemed that a dose as low as 40 to 70 rem may induce pituitary tumors. These findings, representing only a part of a large scale experiment, indicate that ionizing irradiation can produce pituitary tumors in at least one strain of mice. The authors emphasize that the tumors were induced in mice by a single exposure to ionizing irradiation, that they were about four times more frequent among females than among males, and that neutrons appear more efficient in inducing these neoplasms than gamma rays.

Mongolism.—Lazar reconsiders some of the factors that have been mentioned in the literature as etiological factors in mongolism. Studies were made on 129 Mongoloid males and 80 Mongoloid females admitted to the Willowbrook State School of New York State during the three year period from 1948 to 1951. Nothing was found to substantiate the claims that order of birth, age of parents, previous health of the mother, number of abortions, religion, or economic status had any effect on the birth of Mongoloid infants. The presence of the more typical signs of mongolism is confirmed by examination. The Rh factor does not appear to be of significance. An attempt to stimulate the pituitary gland by means of x-ray radiation was unsuccessful. The Mongoloid brain is abnormal at birth, and it would seem improbable that treatment of the pituitary after birth would cause any marked change in the complex pattern of the brain. In the young age group of state school admissions studied, approximately 25% were Mongoloid; this indicates that Mongolian idiocy constitutes an important problem in the care and treatment of mental retardation.

Effect of Sodium Depletion on Size of Heart.—The area of the cardiac silhouette is often reduced by a rice diet of low sodium content. This observation, first made by Kempner, has interested many investigators. Ornstein and Lercher report observations on seven patients in whom the relation between the size of the heart and the sodium intake are well documented. The first five of these patients had been placed on a sodium depletion diet because of hypertension. It was demonstrated that reduction of sodium intake reduces the size of the cardiac shadow in patients with essential and malignant hypertension. When the sodium intake was augmented, the cardiac shadow again showed a relative increase in size. In a patient, who had

periodic attacks of asthma, it was noted that his blood pressure rose during such episodes. When he was put on a low sodium diet, his asthma disappeared and his weight decreased. The authors noted this change frequently. They cite histories of two patients with asthma; these demonstrate that in cardiac asthma sodium depletion reduces the cardiac silhouette in the roentgenogram and favorably affects the asthmatic state.

- Pathogenesis of Hypochromic Anemia. C. deSaussure.—p. 283.
- Socialized Medicine in Great Britain. U. R. Bryner.—p. 285.

Brain Abscess in Small Infants.—Johnson and associates present the histories of three young infants all of whom succumbed to brain abscess. The ages of the infants were 12 days, 22 days, and 2½ months. One of the cases occurred in 1948 and two in 1950. Two of the infants apparently acquired the infection before or at birth; their mothers had severe respiratory infections. The third child was rehospitalized when about 2½ months old with purpuric spots over her whole body. The results of necropsy indicate thrombocytopenic purpura that had caused a series of hemorrhages of the brain. It is suggested that whenever a mother has even a slight respiratory infection at the time of delivery, the infant should receive either chemotherapy or antibiotic therapy to prevent, if possible, the occurrence of brain abscess. The number of brain abscesses in infants under one year reported in the literature is small. The authors briefly cite some earlier reports and say that all infants, except one, died.

Bilateral Mastectomy for Breast Cancer.—Sanders and Griffin point out that the treatment of breast cancer judged by the 5 and 10 year survivals is unsatisfactory. Since breast cancer has come to be regarded as a systemic disease, showing both a hereditary predilection and marked endocrine susceptibility of a bilateral paired organ system, it is being realized that the same group of factors responsible for the development of cancer in one breast may well continue to act to produce, after a varying period of time, cancer in the contralateral breast as well. The incidence of bilateral breast cancer is estimated by some authors at around 10%. The authors recommend for unilateral cancer a technique of bilateral mastectomy that embodies a simple but complete mastectomy on

the contralateral side and a radical Halsted-Haagensen mastectomy on the involved side. Since skin grafting will always be necessary to complete the closure, thick split skin grafts are first cut from the thigh and an occlusive pressure dressing is applied to the donor site before beginning the mastectomy, in order to avoid inadvertent transplantation of cancer cells. The grafts are stored in sterile saline packs until needed. The skin incisions are then outlined on the chest in ink, employing a transverse Stewart incision on the noncancerous breast, which merges with a Haagensen-type incision outlined about the involved breast. Skin flaps are then cut very thin and very widely beginning on the lateral aspect of the noncancerous breast, and resecting the innocent breast as completely and anatomically as possible, progressing from the lateral chest wall medially, in other words, in a cancerwards direction, but pausing at a safe distance (one handbreadth) from the cancer margin in the involved breast before proceeding farther. The simple mastectomy is thus completed, except for medial detachment from the chest wall, before skin flaps are cut on the cancerous side. The further steps of the operation are described and illustrated, and several case histories are presented. The authors feel that the fear that the operation will prove too formidable for the average patient is unfounded. The patients are allowed out of bed and are usually ambulatory by the second postoperative day. The dressings are removed on the seventh postoperative day at which time sutures and drains are also removed. Simple dressings usually suffice from then on. The authors found that unilateral mastectomy patients often expressed the wish that the opposite breast had been removed at the original operation; and many, on being queried, admit that they find the remaining breast a nuisance. Regarding the preference of some surgeons to do the operation in two stages, the authors feel that this is a violation of the principles of cancer surgery of resection in continuity.

Perennial Rhinitis.—According to Putman perennial rhinitis is one of the most important upper respiratory disturbances, but many patients with mild forms never consult a physician. It is a forerunner in about 50% of the cases of asthma. Many of these patients will not seek medical aid until they wheeze or have sinus trouble or nasal obstructions from polyps. Brief attacks of nasal itching, sneezing, and runny or stuffy nose are the most frequent symptoms; they may last for from a few minutes to several hours. Some patients feel as though they have a cold most of the time. Inhalants such as insect sprays, paints, varnishes, oils, perfumes, occupational dusts and odors, fumes, and smokes will aggravate or incite attacks of rhinitis. Ingestants oftenest responsible are cereals, nuts, chocolate, fish, fruits, milk, eggs, spices, and vegetables. Coffee, tea, alcohol, beer, and soft drinks are sometimes exciting factors. Almost any drug taken orally may cause an attack. Infection plays an important role in allergic rhinitis. The membranes of the allergic nose have a weakened resistance, partly because the circulation is impaired in the boggy tissues. The author feels that even the mildest case of perennial rhinitis deserves investigation. The complete avoidance of all offending agents is an ideal goal but hard to achieve. Desensitization becomes necessary when relief is not obtained by avoidance of the offending factors. Caution is important if injections are employed for desensitization; they should not be given too often. Furthermore, aspiration should always be done after the needle is inserted and before injection is made. If blood is obtained, the needle should be withdrawn and reinserted; then aspirate again before injection is made. Nasal polyps and sinus disease should be treated. The use of autogenous vaccines, x-ray treatments, antibiotics, cortisone, and corticotropin are of benefit at times. An attempt should be made to aid the patient in solving his emotional problems. The use of various drugs and measures to reduce the swelling of the nasal mucosa brings about symptomatic relief only.

Culdoscopy: Plea for Wider Application.—Colwell reviews his experiences with culdoscopy in 60 women observed in a general gynecologic service. It was used in 26 patients with suspected ectopic pregnancy, and in 9 of these this diagnosis was verified. Tubal pregnancy was never proved after it had been ruled out by culdoscopy. The next most frequent indication for culdoscopy was adnexal pain. In 2 of these 10 cases, the cause of the pain was not discovered either at culdoscopy or by subsequent observation. In the remaining eight patients, the diagnoses were evenly divided between endometriosis and salpingo-oophoritis. Other indications for culdoscopy were menorrhagia, adnexal mass, amenorrhea, sterility, and masculinization. The patient is given an enema 9 to 12 hours prior to examination. The bladder is catheterized immediately prior to culdoscopy when the patient is in lithotomy position for bimanual examination. Meperidine (Demerol) hydrochloride, 100 mg. with scopolamine 1/150 grain (0.4 mg.), is given intramuscularly one hour prior to examination; and 50 to 100 mg. of meperidine is given intravenously immediately prior to insertion of the trochar. With the patient in the knee-chest position, the posterior fornix of the vagina herniates upward and forward between the two uterosacral ligaments and over the posterior surface of the uterus. At the highest point of the concavity about 5 cc. of 1% procaine (Novocaine) hydrochloride solution is injected into the vaginal mucosa. The perineum is elevated with a Sims speculum, and the cervix is drawn forward and slightly downward by a tenaculum toward the symphysis. The trochar is locked into the cannula, and, with a sudden thrust, the trochar is introduced into the peritoneal cavity. The trochar is withdrawn from the cannula, and the sterile culdoscope is inserted. The telescope has a range of 4 in. (10.16 cm.) beyond the tip of the cannula so that it may be moved in or out, anteriorly or posteriorly, and laterally. More structures may be brought into view by manipulation of the uterus with the tenaculum on the cervix or by suprapubic pressure created by an assistant. No serious complication occurred, except that in one patient the trochar entered a serous cystadenoma and about 75 cc. of clear serous fluid was obtained. When this patient was operated on four weeks later, there was no evidence of the previous accident. Culdoscopy deserves wide application, but it should not be employed to confirm the obvious. The patient in shock who gives a typical history of ectopic pregnancy and in whom is found a crepitant, bulging cul-de-sac and an excruciatingly tender adnexal mass certainly should not be subjected to culdoscopy.

Fibrotic Nontraumatic Stenosis of Common Duct.—The occurrence of fibrotic benign stenosis of the terminal common duct is reported in five men and six women between the ages of 33 and 78. Söderlund believes that this stenosis resulted from a chronic inflammatory process in the wall of the common duct. Such an inflammation was observed in 3 of the 11 patients; there was thickening of the wall of the duct, which contained turbid mucopurulent bile, and the duct was embedded in an indurated, inflamed hepatoduodenal ligament. In seven patients, the duct above the stenosis was more or less pronouncedly dilated, with a diameter varying from 15 to 35 mm., reaching the width of the small intestines in one patient. Cholecystectomy had been performed previously for gallstone in nine patients; the gallbladder and common duct of the remaining two patients did not contain any calculi. Pain of the biliary colic type was the presenting symptom in 10 patients; jaundice was observed in 7. Treatment consisted of choledochoduodenostomy in 10 patients, and choledochogastrostomy in 1. Of the 11 patients, 9 were followed up for from 2 to 10 years and 1 for 18 months; 1 was operated on only recently. Immediate and lasting relief from distress resulted from the treatment in nine patients, while in the remaining two recovery occurred gradually after some time.

Vagotomy for Recurrent Peptic Ulcer.—Between 1947 and 1950, 26 patients were subjected to vagotomy because of post-operative recurrence of peptic ulcer. Follow-up was done one to five years after the vagotomy on 21 patients. In 5 of the 21 the operation performed before the vagotomy was Billroth 1, in 13 Billroth 2, and in 3 a gastroenterostomy. The interval between the operation and the appearance of peptic symptoms in patients who underwent gastroenterostomy was 11 years; in those who underwent Billroth 1 operation it was 2 years and 9 months; and in patients who had the Billroth 2 operation it was 1 year and 7 months. Of the 21 patients, 12 were satisfied with the results of the vagotomy; of these, 6 had earlier undergone Billroth 2 operation, 1 gastroenterostomy, and 5 Billroth 1. Six patients, five of whom had been operated on by the Billroth 2 method and one who had undergone gastroenterostomy, were satisfied with the results of the vagotomy. Two who had had Billroth 2 operation were not satisfied with the result of the vagotomy, and one who had had a previous gastroenterostomy was dissatisfied. Results of vagotomy for postoperative peptic ulcer could thus be considered as good in 87.5% of the patients. This figure is compatible with those reported by other workers in this field. In no patient was vagotomy followed by atony of the stomach, severe diarrhea with nutritional disorders, or disturbed gastric motility. No definite signs of recurrence were observed. In view of the difficulties in performing resection for jejunal ulcer and the risks incurred by such an operation, vagotomy must be considered a useful method.

Hypothermia with Autonomic Block.—A technique described as induced hypothermia with autonomic block was used for major surgery in 26 patients. Premedication consisting of meperidine (Demerol) hydrochloride and Phenergan (10-[2-dimethylamino-1-propyl]phenothiazine) was given intramuscularly three to four hours preoperatively. An intravenous infusion of isotonic sodium chloride solution or 5% dextrose was set up one hour later as a vehicle for administration of the "lytic cocktail" consisting of 50 mg. (2 cc.) of Chlorpromazine (10-[γ -diethylaminopropyl]-2-chlorophenothiazole), 100 mg. (2 cc.) of meperidine hydrochloride, and 50 mg. (2 cc.) of Phenergan. The initial injection was generally 2 cc. followed by supplements of 0.5 to 1 cc. at intervals of 15 to 20 minutes. Patients who were not asleep before the beginning of the infusion became unconscious after the first or second dose of the cocktail. With one exception, this occurred within 30 minutes of administration of the first dose. The rapidity of onset of unconsciousness and its depth were a guide to the time to begin surface cooling. On an average this was one and a half hours before operation. Ice-bags were first placed on the groin, and, in the absence of a response to this, the body was completely covered with ice. Shivering was looked for closely, and its occurrence taken as an indication for a further dose of the cocktail. In all patients cooling was continued until the patient was taken to the operating room. During the period of cooling, observations were made of blood pressure, pulse, and respiration every 15 minutes. The principles of anesthesia did not vary from those used for patients subjected to abdominal and thoracic surgery under normal circumstances. Replacement of blood loss was carried out as for normal cases. During the operation observations were made as for the period of cooling. On return to bed the patients were covered with a single sheet, and the appearance of shivering was an indication for the application of further covering. It was explained to the nursing staff that for the first 12 postoperative hours they were to consider their patients poikilothermic and to treat them as such, removing blankets should a hyperpyrexia occur. In two of the five deaths, one occurring during surgery and four within 24 hours to 16 days postoperatively, hypothermia may have contributed to the outcome. From their observations of the changes that occurred in the respiratory system, the cardiovascular system, and the body temperature with the amount of bleeding, the authors conclude that the danger of serious cardiac irregularity at temperatures lower than 28 C is real and is particularly imminent if cardiac manipulation is required. The difference in oxygen consumption between a patient at 82.4 F and 77 F is insufficient to warrant the extra risks involved by proceeding to lower temperatures. The reduction in bleeding during hypothermia was not always as pronounced as it was expected. At low temperatures the prolongation of the clotting time and/or bleeding time has on occasion been a source of embarrassment. It seems that hypothermia might be an added risk in patients whose myocardium is damaged. The indications for hypothermia would seem to be (1) when a degree of hypotension is required to control hemorrhage either for patients in whom large blood loss is expected or in whom even a small blood loss will embarrass the work of the surgeon; (2) in patients with a severe degree of anemia that can-

not be corrected before operation; (3) in operations on the heart and great vessels in which it may be necessary to cut off the cerebral circulation for a period of time; and (4) in thyrotoxicosis that cannot be controlled by medical treatment.

Hexamethonium Bromide in Treatment of Acute Pancreatitis.—Two men, aged 64 and 52 years, with acute pancreatitis confirmed by exploratory laparotomy remained in great pain after the abdomen was closed without drainage. A bilateral posterior splanchnic block was performed with 1:2,000 tetracaine (Amethocaine) hydrochloride in the older patient. The relief from pain was dramatic, but pain began to recur after six hours. It seemed reasonable to believe that ganglion-blocking agents, such as hexamethonium bromide, would relieve pain similarly to splanchnic block and would have none of the difficulties or dangers of repeated splanchnic blocks. The patient then was given orally 250 mg. of hexamethonium bromide via an indwelling Ryle's tube twice a day. Pain disappeared after six hours, and the next day it was possible to assess the patient as convalescent. Treatment with hexamethonium was continued for five days, the patient being discharged as cured on the 10th day. The other patient was given 250 mg. of hexamethonium bromide as soon as he was conscious, and administration of the drug was continued twice a day for the next seven days; every four hours blood pressure readings were carried out. The following day he was free of pain, and his convalescence was smooth and uneventful. He was discharged as well 12 days after the operation. The inflammatory changes in the pancreas of patients with acute pancreatitis bear a striking resemblance to thrombosis or emboli of the main vessels to other intra-abdominal organs and the upper and lower limbs. Gangrene, sloughing, and suppuration follow gross disturbances of the blood supply, and the severity of the symptoms may be related to the extent of the infarction. The relief of pain and the improvement in the general condition produced by the ganglion-blocking drugs in these two patients and in two additional patients treated with equally successful results since this paper was submitted for publication, were contrary to previous experience. Although the disease was robbed of its terrorizing pain by the drug, it cannot affect the established gangrenous or suppurative process in a gland that must be subjected to drainage. The authors feel that a vascular catastrophe is the causative factor in acute pancreatitis, and further studies along these lines may lead to a better understanding of the disease and simplify its treatment.

Selection of Patients with Congenital Cardiac Defects for Surgery.—Commissurotomy according to Bailey and co-workers' technique was performed on 10 patients between the ages of 22 and 37 years with mitral stenosis. Combined widening of the narrowed orifices was done in 6 of the 10 patients, while digital valvotomy was sufficient in 4. Blunt procedure whenever possible was used with the combined technique for the exact demonstration of the valvular angles so that the valvular segments could be spared by the subsequent incision of the

fibrous bands. Incision rather than digital dilatation of the orifice was done because a recurrence caused by repeated shrinking of the ring of the valve may soon be expected from mere dilatation. The authors agree with Bolton and co-workers that the orifice should be enlarged only by incision to lessen the risk of mobilization of calcium deposits. Small pleural effusions and pericardial friction were observed in all patients, but more extensive pericardial effusions were not. Postoperative administration of Irgapyrin, a proprietary containing equal parts of phenylbutazone and aminopyrine was used satisfactorily for relief of pericardial pain and restoration of temperature to normal. Postoperative auricular fibrillation occurred in two patients and was controlled by quinidine and procaine amide respectively. Routine preoperative and postoperative oral administration of the latter drug in small doses is recommended. All the patients survived the operation. Follow-up for 12 months revealed considerable improvement in four patients and good improvement in the other six. Diastolic murmur disappeared in four patients, became less pronounced in five, and was unchanged in one. The authors divide the clinical aspect of mitral stenosis in four groups on which the indications for surgical intervention may be based. The first group comprises patients whose work capacity is not impaired and in whom, therefore, surgical intervention is not indicated. The second group comprises those with slightly impaired work capacity for whom surgical intervention is indicated. For patients with definitely impaired work capacity who form the third group, operation is necessary, while patients with dyspnea at rest and considerable complaints associated with the slightest physical activity who form the fourth group should not be operated on. From their experience and from the results obtained by other workers in 1,346 cases collected from the literature, the authors state that improvement was obtained in 92.5% of the patients who survived the operation and that the operative mortality was 10.4% including the relatively high mortality in the first patients operated on. No patients became worse as a result of the commissurotomy and surgical intervention is to be considered a great progress in the treatment of mitral stenosis. Surgical treatment of mitral insufficiency is still in its initial stage, and the authors have no experience with it. Surgical technique for stenosis of the aorta is still in the developmental stage. Of two patients operated on by the authors, one died, while the other obtained considerable improvement. In contrast to the surgical treatment of mitral stenosis, severe valvular calcification is not to be considered as contraindication to surgical intervention but may jeopardize its permanent success.

Treatment of Tuberculous Meningitis.—Of 104 children with tuberculous meningitis treated between 1947 and 1953 at the Children's Hospital in Zurich, results were evaluated in 62, but they were not in the remaining 44 for the following reasons: follow-up of less than one year; lack of bacteriological diagnosis; admission to the hospital after more than one week of previous treatment elsewhere; and death occurring within the first week after admission. Seven of the 62 patients were given high doses of streptomycin and all of them died. Of seven additional children who received low doses of streptomycin for a short period or who were given several short courses of treatment at long intervals, five died. Of the remaining 48 children who were treated with low doses of streptomycin combined with sulfones or p-aminosalicylic acid for a long period, 30 were cured (a survival rate of 63%). Five of the 30 children had suffered permanent impairment consisting of hydrocephalus with organic psychosyndrome in 3 and of auditory damage in 2. Twenty-eight of the 30 survivors had mild vestibular damage. Tuberculosis of bone and

joints occurred in three children after recovery from the tuberculous meningitis. Transitory complications in the course of tuberculous meningitis consisted of pareses, hydrocephalic bouts, psychic disturbances, and disturbances of the autonomic nervous system. Fatalities were distributed equally over the first nine months of treatment. The mortality was higher among children in the first three years of life (52%) than in older children (22%). The higher mortality among the younger children may be related to the difficulty of making an early diagnosis in infants. The prognosis of tuberculous meningitis depends mainly on the stage of the disease at the time treatment is started (stage of pure meningitis, stage of sensory and peripheral nerve involvement, or stage of coma). The death rate was not increased among the children in whom meningitis was associated with miliary tuberculosis; 7 of 21 children with meningitis and miliary tuberculosis died, and there were 6 deaths among 21 children without miliary tuberculosis. In contrast to this, the prognosis is poor in patients in whom meningitis occurs while they are being treated with streptomycin for miliary tuberculosis; four of six children in this group died. The protein, chloride, and sugar values in the spinal fluid at the time of the institution of treatment did not play a decisive role with respect to prognosis. Since March, 1952, 18 children were given combined treatment with streptomycin and isoniazid and occasionally with *p*-aminosalicylic acid. This combined therapy proved highly effective and its great advantage is its shorter duration; the one and a half year follow-up period, however, is too short to permit definite conclusions.

Combined Treatment of Tuberculous Meningitis with Streptomycin, Para-Aminosalicylic Acid, and Isoniazid.—Of 141 children with tuberculous meningitis receiving combined treatment with streptomycin, *p*-aminosalicylic acid, and isoniazid at a children's hospital in Athens, Greece, 72 died and 69 recovered; 12 had recurrences and 5 of these died. The total mortality was 51.06%. Mortality was particularly high among children less than two years of age, among those who had been treated previously with streptomycin for other tuberculous conditions, and among those with meningitis associated with miliary tuberculosis. Changes of the fundus of the eye occurred in 79 patients. Vestibular and auditory disturbances were less frequent with the combined treatment than with streptomycin alone; there were only four cases of deafness. Endocrine disturbances were observed in 35 patients, psychic disturbances in 18, and mild renal disturbances in 30. Disturbances of the liver occurred in only seven patients; in six of these the size of the liver was increased and in one there was jaundice. Cutaneous manifestations were observed in 10 children. At present combined treatment of tuberculous meningitis is carried out with 400 to 800 mg. of streptomycin daily according to the age of the patient and the severity of his condition; intrathecal doses of streptomycin vary from 25 to 50 mg. daily and suboccipital doses from 5 to 10 mg. daily. Three to 6 gm. of *p*-aminosalicylic acid is given by mouth daily. Isoniazid is administered orally or intramuscularly in doses of 5 to 10 mg. per kilogram of body weight daily and in intrathecal doses of 0.5 to 1 mg. per kilogram of body weight daily. The duration of this combined treatment may be shortened to 3 to 6 months as compared to that of 8 to 12 months with streptomycin alone.

Detection of Lying.—According to Ames it has long been known that when the mind seeks to conceal, the body may betray fear and guilt by emotional disturbances. Attempts to measure bodily reactions to guilt date back to antiquity. After

citing some ancient customs and stories the author mentions 19th century attempts to measure bodily reactions to guilt scientifically and then briefly reviews more recent efforts to detect lying by registering the changes in blood pressure and respiration that accompany emotional stress. The method of using Keeler's polygraph or lie detector is described, and the attitude of the courts about the admissibility of lie detector results as evidence is discussed. A lie detection test is a stressful experience, whether one is guilty or innocent. The persons who use the instrument are aware of its more obvious limitations. They know that some persons will be unsuitable for testing because of circulatory or respiratory disease. They know, too, that results are valueless if a subject is too feeble-minded or mentally deranged to understand what is going on. They know that psychopaths have no moral sense about lying and so will not register any emotional reaction. They are aware that the phlegmatic type of person shows very little disturbance, and the emotional, anxious type shows a great deal. There has been some retreat from the earlier enthusiasm about the value of the polygraph. The author feels that the proper perspective can be gained when it is remembered that all the lie detector does is to measure at two points the generalized physiological reaction to stress. It does this by combining two simple techniques that have been used by the medical profession for decades. There is nothing magical about the instrument, and to trade on the fear and the ignorance of suspects by assuring them that the lie detector never lies, because it is some mysterious and infallible invention of science, is a reprehensible way of dealing with a person whose guilt is in doubt. All that one can say definitely is that an emotional reaction is a physiological event. It is a nonspecific event; there is no special reaction peculiar to guilt.

*Prognosis of Tuberculous Meningitis in the Child. Bernheim, J. Lanternier and Robert-Rougier.—p. 821.

Prognosis of Tuberculous Meningitis in the Child.—Study of 224 children with tuberculous meningitis showed that survival and recovery depend primarily on the age of the child, the time at which treatment is begun, the extent and severity of the encephalitic symptoms then present, the therapeutic measures employed, and the strictness with which the treatment is pursued. Approximately two-thirds of the children with tuberculous meningitis now recover, and the late results, taken as a whole, are encouraging. Children less than a year old, in whom the premonitory symptoms are few or pass unnoticed, are usually in poor condition on arrival at the hospital; none of that age group in this series survived. Treatment must be started early, both in infants and in older children. Particular care should be used when fever persists or recurs in children with apparently mild primary infections in the lungs. The slightest abnormal development in the course of a primary infection should be the signal for prompt lumbar puncture, which often makes it possible to treat tuberculous meningitis before it has become clinically established, thus improving the prognosis very considerably. The neurological state of the child when treatment is started is more important than its physical condition. Coma, mental confusion, and epileptic attacks have an ominous significance, and hemiplegia, even when slight, ophthalmoplegia, and a simple Babinski sign also indicate a need for close daily surveillance. Failure to recover Koch's bacilli on lumbar puncture has little prognostic value because the meningitis is equally virulent whether the cultures are negative or positive. The coexistence of pulmonary miliary tuberculosis and tuberculous meningitis does not seem to be particularly detrimental, but it does necessitate prolonged treatment. Examination of the eye grounds provides valuable information. The appearance of new granulations or tubercles is often indicative of relapse. Treatment should then be intensified or continued, even though the clinical and laboratory findings suggest that it may safely be terminated. Slight papillary edema without signs of blocking usually disappears in two or three months, but edema seen later during treatment and associated with evidences of blocking is serious and should lead to ven-

tricular puncture. Surgical treatment is now limited to trepano-puncture of the two frontal ventricular horns with instillation of streptomycin. This simple procedure has proved lifesaving in many cases. General antibiotic treatment is usually continued for from 8 to 12 months or until the cerebrospinal fluid becomes normal.

Acetylcholine in Treatment of Neurosis.—Since it had been asserted by some investigators that acetylcholine is of value in the treatment of some anxiety states, particularly in those accompanied by tension, MacLay decided to try this drug in certain patients who were responding insufficiently or not at all to psychotherapy. He began with a dose of 0.06 or 0.08 gm. in 1 cc. of water. He gradually increased this dose until 0.2 gm. had been reached. Although some patients tolerate 0.25 gm. or more, caution is necessary with this dose. Immediately after the injection, the patient feels acutely ill; the pulse slows or stops; and there is a brief loss of consciousness. The author has learned not to feel undue concern if the patient is pulseless for 25 seconds. The face is usually red and congested, and this is followed by pallor. Within a minute or two, the patient is able to get up and walk away. MacLay prefers to give the minimum dose that produces unconsciousness. Administering 1.5 grains (0.1 gm.) of secobarbital (Seconal) sodium beforehand has proved helpful in some patients who feel severe discomfort from the acetylcholine injection. As antidotes for emergencies the author keeps on the tray epinephrine (Adrenalin), nikethamide (Coramine), and atropine, and a long needle just in case an intracardiac injection is required. He has used acetylcholine so far in 11 patients whose histories are presented. Three appeared to obtain considerable benefit. The total impression was that it will be worth while to continue using this new remedy in selected patients.

Therapy of Hydrocephalus in Tuberculous Meningitis.—Despite progress in treatment by chemotherapeutics and antibiotics, it is often impossible to arrest tuberculous meningitis during the exudative stage. During the chronic state the normal relationship between production and resorption of the cerebrospinal fluid often becomes impaired, and a more or less severe hydrocephalus results. On the basis of four case histories, which were selected from a large number, Janssen and Wilms show how difficult it is to make a prognosis. The children were in a comatose state, most of them for months and one for more than half a year. They had to be fed by tube. Choked disk and other clinical signs indicated the presence of hydrocephalus, which was so severe that there was

little hope that life could be preserved. It seemed that mental and physical defects would result even if death could be prevented. After temporary interruption, treatment with streptomycin was resumed, however, and the child eventually recovered without mental defects, although hearing was defective. Results obtained in the other three cases were similar. The authors advise great caution with regard to surgical interventions for hydrocephalus, because they found that such treatment was ineffective in several cases and treatment with antibiotics may arrest hydrocephalus even in chronic cases of tuberculous meningitis.

Coronary Heart Disease and Physical Activity of Work.—Study of the relations of physical activity and inactivity in work to coronary heart disease among middle-aged men suggested the following hypothesis: Men in physically active jobs have a lower incidence of coronary heart disease in middle age than men in physically inactive jobs. More important, the disease is not so severe in physically active workers, in whom it tends to appear first in relatively benign forms, especially angina pectoris, and to have a smaller early case-fatality and a lower early mortality rate. This hypothesis was tested in three ways, with the following results. 1. The early mortality rates of physically more active workers (conductors and postmen) were lower than those of physically less active workers (drivers and switchboard operators). 2. Analysis of the statistics available for various occupations showed that the mortality from coronary heart disease in groups doing heavy work was rather less than half that of the groups doing light work. 3. Classification of the occupations of men dying of coronary heart disease as given in a trial sample of death certificates showed that fewer heavy workers die in the first clinical episode of the disease. This supports the belief that physical activity in work is associated with less severe forms of coronary disease. Many other factors—physical and psychological as well as occupational and social—enter into the problem, and it is quite possible that unfavorable factors cluster in certain occupational groups. Nutritional differences between various groups and classes in particular may prove important in their relation to atheroma, which is the basis of the disease.

Cortisone and Rheumatoid Disease.—Cortisone acetate, in doses of from 50 to 75 mg. a day, has been given orally to 27 patients with rheumatoid disease for an average of 19 months. Each patient was paired with a control chosen from a group of 1,000 not receiving cortisone, and in every case the pairs were matched as closely as possible in age, duration of disease, and distribution of affected joints. The patients treated with cortisone and the controls were then compared in respect to (1) stiffening of joints with rest; (2) need for analgesics; (3) physical ability; (4) erythrocyte sedimentation rate; (5) hemoglobin values; (6) x-ray changes; (7) strength of grip; and (8) well-being. The results of the comparison indicate that the course of rheumatoid disease is not favorably affected by long-term cortisone treatment, in spite of the early benefit enjoyed by some patients. The relative adrenocortical deficiency and the acute deficiency at times of stress that may follow the withdrawal of cortisone acetate after prolonged therapy should also be considered in weighing the evidence for and against its long-term use. Death has undoubtedly been hastened by cortisone therapy in some cases. These findings do not exclude the possibility that certain types of rheumatoid disease may be bene-

fited by prolonged administration of cortisone acetate. Present knowledge of the metabolism of corticosteroids does not warrant excluding them from participation in the pathogenesis of rheumatoid disease.

Pentamethonium in Hypertension.—Pentamethonium was given to 35 patients with chronic and acute hypertension. Thirty patients were treated on an ambulatory basis and received the salt orally in doses of 20 cg. at first every 12 hours and later four to six times daily for from four to eight weeks. A fall of from 20 to 60 mm. Hg occurred in the systolic pressure whereas the drop in the diastolic pressure was less pronounced. This decrease was especially marked during the first three hours after the administration of the salt with disappearance of headache, dizziness, and dyspnea. Vomiting and constipation developed in eight patients to whom laxatives were given; a few patients complained of disturbances in micturition and the dose of pentamethonium was lowered. In a follow-up one month after discontinuation of the therapy the improvement was still present in 40% of the patients, whereas the arterial pressure had a tendency to return to the initial values in 52%. The therapy had to be discontinued in 4% because of tachycardia, headache, fainting sensation, and gastric disturbances; the treatment had failed in 4% despite the administration of doses as high as 120 cg. of pentamethonium daily for one week. Five patients with hypertension and symptoms of intracranial hypertension and papilledema who were hospitalized because of severe hypertensive attacks were given the salt intravenously in initial doses of 10 mg., increased gradually to 50 mg., administered in isotonic sodium chloride solution every 8 to 10 hours daily. The blood pressure dropped within 10 minutes, and drowsiness, headache, and vomiting disappeared. The induced hypotension was greater and occurred more abruptly in these patients, but the action of the salt lasted for a much shorter time. The intravenous route of administration is contraindicated for prolonged use and, therefore, for patients with chronic hypertension, since it is difficult to find a proper single dose and to maintain a constant hypotension even if the drug is given two or three times daily.

This route may prove useful in patients with acute forms of hypertension such as pseudoremia and eclampsia of pregnancy. Whenever pentamethonium is given intravenously, the patient should be watched carefully to prevent a possible collapse.

Bulbar Poliomyelitis Following Tonsillectomy.—Mackay presents a family of three children, aged 8, 5, and 3 years, who had had recurrent upper respiratory infections, with ear and chest complications. Because of this and because the risk of infection from poliomyelitis was thought to be remote, the tonsils and adenoids were removed. The operations were carried out on Nov. 26, 1952. On Dec. 3, all three children had fever and temperature up to 101 F, and this fever and malaise persisted. On Dec. 8, child A, aged 8, appeared very ill, had difficulty coughing and swallowing, and was admitted to the hospital. The cerebrospinal fluid showed cells, and a provisional diagnosis of bulbar poliomyelitis was made. The following day some weakness of the left side of the face was present; the palate moved but swallowing was impossible. On Dec. 9, child W was admitted with a temperature of 102.4 F, some neck rigidity, and weakness of the left upper arm. Twenty-four hours later pharyngeal paralysis appeared, and he died on Dec. 11, in spite of intravenous therapy, oxygen, etc. Child A required intravenous therapy for five days, and, after causing some anxiety, she made a complete recovery. The youngest child, apart from a few days of fever, showed no evidence of poliomyelitis. The author reviews the literature on the relationship between bulbar poliomyelitis and tonsillectomy and concludes that the risk is not negligible. Even those who deny any causal relationship between tonsillectomy and poliomyelitis agree that elective surgery should be postponed during an epidemic. The position with regard to diphtheria-pertussis immunization is perhaps not quite so clear. In spite of the fact that cases have been reported in which an injection appears to have produced a locus minoris resistentiae and converted an otherwise nonparalytic into a paralytic infection, the association is rare and still lacks proof. But when poliomyelitis is abnormally prevalent, the possibility that immunization may add an extra risk must seriously be considered.

Function of Adrenal Cortex in Insane.—Lingjaerde examined the 17-ketosteroid excretion in 93 insane patients and the reaction to epinephrine, corticotropin (ACTH), and insulin in 122 insane persons. No patient showed abnormal reaction to any of the tests. Low excretion of 17-ketosteroids was especially connected with the apathy-stupor syndrome, and a high excretion seemed to be connected particularly with psychopathological symptoms, perhaps to be called the alarm syndrome. So far no definite support has been found for the concept that adrenal deficiency is characteristic of any definite form of mental disease or any psychopathological syndrome.

with the possible exception of acute delirium. In not a few patients, especially those with puerperal psychosis and involution melancholia, there were signs that might point to a hypopituitarism. Hypoglycemia was prolonged in more than half the insulin tolerance tests. This "hypoglycemia unresponsiveness" as a rule occurred in patients who refused to eat and had urobilinuria and ketonuria. The insulin reaction was returned to normal with increased administration of carbohydrates, and the urobilinuria and ketonuria disappeared when the insulin reaction became normal. In some insane patients, especially in the active phase, there is increased carbohydrate need that may depend on either stress or failure to utilize carbohydrates. When such patients refuse food, a relative carbohydrate deficiency easily occurs that will soon lead to disturbances in the carbohydrate metabolism and can cause disturbances in the function of the liver and certain endocrine organs and thus express itself not only in hepatic symptoms but also in an abnormal insulin-hypoglycemia reaction. It is thought reasonable to assume that the abnormal insulin-hypoglycemia reactions in insane persons are due to the effect of carbohydrate undernourishment, alone or in combination with other factors.

*Intradermal Administration of Corticotropin in Treatment of Whooping Cough. G. Di Gruttola.—p. 719.

Corticotropin (ACTH) in Whooping Cough.—Corticotropin was given to 16 children between 1 month and 3 years of age with whooping cough. Three infants were hospitalized; the others were treated on an ambulatory basis. The paroxysmal phase of the disease had been present in nine for one week, in five for 10 days, in one for 20 days, and in one for two months. A daily dose of 3.5 mg. of active ultrafiltrable fraction of corticotropin was injected intradermally in the forearm. The treatment was continued for from 5 to 13 days. In few cases only corticotropin was combined with antibiotics. The drug was tolerated well, and its good effects began to appear after 24 hours. The number and intensity of the attacks were reduced to half by the second day; cyanosis and vomiting disappeared by the third day; and appetite and weight began to increase and general condition to improve. A follow-up some time later revealed that all the children were definitively cured; they had gained weight and were in good general condition. The mechanism of action of corticotropin in whooping cough is obscure.

*Hyperglycemia Without Glycosuria: Physiopathology and Treatment. H. Lestrade.—p. 1482.

Hyperglycemia Without Glycosuria.—The classic concept of diabetes mellitus does not account for the condition of hyperglycemia without glycosuria, which is, in fact, occasionally found. Sometimes it develops in the course of diabetes. Actually, this condition represents a nephropathy and not, as might be presumed, a spontaneous remission in the diabetic patient's condition. Based on the fact that the amount of glucose burned by diabetics is the same as in normal persons, the new concept that diabetes results from an inability of glucose to enter a cell, rather than a disturbance in glycometabolism, explains the possibility of hyperglycemia without glycosuria. This syndrome always has an unfavorable prognosis, since it indicates the presence of renal lesions. There are also usually generalized vascular lesions, especially retinitis. Its treatment requires the observance of its dual causal mechanism; that is,

the regular diabetic regimen with insulin remains unaltered, but is accompanied by vitamin therapy and limitation of proteins and fats, and electrolytes according to individual tolerance. Testosterone and vitamin B may also be given; and the experimental use of heparin for its proposed ability to improve the lipoprotein balance of these patients should be kept in mind for the future.

*Treatment of Superficial Cancer with Ultra-soft Roentgen Rays. C. T. Schmidt and E. Amdrup.—p. 1590.

Remarks on Cancer of Lip. J. Nordentoft.—p. 1596.

Causes of Cancer of Lung.—Clemmesen and Jensen discuss the marked increase in cancer of the lung in men, especially men in middle life and less well-to-do classes, and review investigations carried out on the cause of cancer of the lung. With reference to occupational causes, the authors find pulmonary cancer to be relatively rare even among workers exposed to carcinogenic substances, with the exception of the miners in the Erzgebirge. Occurrence of increase also in rural districts weakens the concept that contamination of the air may play a contributing part in the action of cancerogenic combinations on the lungs, and further, this assumption cannot explain why the disease has not increased among women and is inconsistent with the increase particularly among younger persons, although a weak indirect supporting effect on factors with strong cancerogenic action cannot be excluded. It is not possible, the authors find, to explain that there are more smokers among patients with cancer of the lung than among control persons except by the assumption of a causative relation. From a biological viewpoint it must be regarded as practically certain that the primary cause of cancer of the lung lies in the agent that more frequently and in greater concentration than any other comes into contact with the affected organ and has been shown to have a weak cancerogenic effect on animals and can therefore with reason be thought to have it on man. The academic proof of the cancer-producing effect of tobacco, for example, can be obtained only by removing the harmful influence of the assumed agent from a population that has already shown itself to react with the disease.

Treatment of Superficial Cancer with Ultra-soft Roentgen Rays.

—Irradiation with ultra-soft roentgen rays, Schmidt and Amdrup state, is a quick and certain treatment of skin cancers less than 2 mm. in thickness. The principle is to give sufficient dosage to the tumor and at the same time treat leniently the deeper normal cells and their blood supply. The treatment is carried out in one session of a few minutes' duration; the danger of radiation necrosis is slight; and the cosmetic results are excellent. If the cancer is allowed to grow to over 2 mm. in thickness the somewhat harder roentgen rays then necessary are more dangerous to the underlying tissue and the risk of recurrence and radiation necrosis is greater. Cancer of the skin was established by biopsy in 77 patients, of whom 48 were between 60 and 80. There were in all 82 cancers. The 69 cancers less than 2 mm. thick were treated with ultra-soft roentgen rays with good results; in one case there was recurrence, but repeated treatment was without complications and the patient is well five years after the treatment. The 13 cancers more than 2 mm. in thickness received slightly harder roentgen rays, with uneventful course in seven cases and complications in the form of recurrence, glandular metastases, or radiation necrosis in six. Follow-up during a five year period revealed 18 deaths; in 14 of these there had been no complications and death was not due to cancer.

BOOK REVIEWS

Rehabilitation Centers in the United States. By Henry Redkey. Compilation of information submitted by 40 rehabilitation centers for first national conference on rehabilitation centers, December 1-3, 1952, under sponsorship of National Society for Crippled Children and Adults and Office of Vocational Rehabilitation, U. S. Department of Health, Education, and Welfare. Paper. \$1. Pp. 128, with illustrations. National Society for Crippled Children and Adults, 11 S. LaSalle Street, Chicago 3, 1953.

This monograph is an outgrowth of the first National Conference on Rehabilitation Centers, as a result of which detailed descriptions of 40 rehabilitation centers in the United States were compiled. It is pointed out in the monograph that "these forty centers probably are representative of all the centers in the country but they do not constitute a listing of every center in the United States. They range from teaching centers which are part of great universities to small curative workshops with one or two therapists serving outpatients." The book contains a general review of rehabilitation centers, teaching and research centers, centers located in and operated by hospitals and medical schools, community centers with facilities for inpatients, community outpatient centers, insurance centers, and vocational rehabilitation centers. It will be most useful to all interested in rehabilitation. In addition to simply listing the names of the forty centers, it contains brief discussions of the activities and problems encountered by each of them. Comparisons are made between the centers, and such interesting data as the approximate cost of the physical plant, the approximate annual operating cost, total floor space, and the amount of personnel in each is tabulated. The wide difference between the rehabilitation centers described is accounted for by the fact that each is set up to meet the specific needs of the community it serves.

Techniques of Tuberculin Testing and BCG Vaccination. U. S. Department of Health, Education, and Welfare, Public Health Service, Division of Chronic Disease and Tuberculosis of Bureau of State Services. Public Health Service publication no. 182. Paper. 55 cents. Pp. 44, with 19 illustrations. Superintendent of Documents, Government Printing Office, Washington 25, D. C., 1953.

This handy, easily read, loose-leaf manual briefly outlines and illustrates the established techniques of BCG vaccination and tuberculin testing. It is intended as a guide to professional technicians in the application of these procedures and as an aid to planning an efficient program for the use of the vaccine as a partial immunizing agent against tuberculosis in persons particularly vulnerable to exposure. The manual provides concise directions for screening candidates for vaccination as well as precautions in the care of equipment and materials needed for proper conduct of both procedures. It will be highly useful to all clinical and technical personnel of health departments, particularly in those areas where detailed instructions for the procedures have not been adopted by local authorities. The manual is clearly printed, and its cost is commensurate with economical distribution.

Ear, Nose, and Throat Diseases for Medical Students. By William McKenzie, M.B., B.Chir., F.R.C.S., Surgeon, Royal National Throat, Nose and Ear Hospital, London. Cloth. \$5.50. Pp. 260, with 95 illustrations. Williams & Wilkins Company, Mount Royal and Guilford Aves., Baltimore 2; E. & S. Livingstone, Ltd., 16 and 17 Teviot Place, Edinburgh 1, 1953.

The aim of this book is to be interesting rather than exhaustive. The author believes that if it can stimulate the English undergraduate medical student to read a larger book on diseases of the ear, nose, and throat, it will have served its purpose. The book is written in a simple, highly personalized conversational style and contains numerous homely observa-

tions and reflections based on the author's experiences in this special field. "Diseases of the ear, nose, and throat," he asserts, "are common in general practice. The specialty is unpopular with medical students and doctors because of the difficulty with various examinations. These need practice but no great intelligence." And again, "Frequent colds is a fact which I record in the notes, but which I treat with reserve. I have two children myself and know how common coughs and colds are in young children—if a dozen children are invited to a Christmas party we are lucky if eight arrive." American otolaryngologists will not always agree with some of the comments expressed, but by and large this will be due to differences of opinion founded on dissimilar experiences and interpretations of medical events.

Salt and the Heart. By Edward T. Yorke, M.D., Attending Cardiologist, Alexian Brothers Hospital, Elizabeth, N. J. Cloth. \$3.45. Pp. 83, with illustrations. Drapkin Books, 36 East 19th Street, Linden, New Jersey, 1953.

This small volume is written for the laity. It deals with the role of salt in cardiovascular diseases. The author is abreast of the time in his discussion of the value of salt and of the role of salt in high blood pressure and in the failing heart. The last few chapters give an analysis of the salt content of various foods. The book should be of value to persons concerned about the low-sodium diet.

A Handbook for Dissectors. By J. C. Boileau Grant, Professor and Director of Department of Anatomy, University of Toronto, Toronto, Ontario, and H. A. Cates, Professor of Anatomy, University of Toronto. Fourth edition. Cloth. \$3.50. Pp. 425, with 26 illustrations. Williams & Wilkins Company, Mount Royal and Guilford Aves., Baltimore 2, 1953.

This excellent book is the product of 17 years of continuous use by the authors in a well-managed dissecting room. The foundation of diagnosis and surgery must be anatomy: He who would repair the machine must trouble to know its parts. The reduction in time available for dissection in the medical course, however, has made good plans and guides increasingly important. Four editions and several reprints of this book are evidence that it has been meeting a need and are evidence of continuous solicitude by the authors and continuous appreciation by other teachers of anatomy. In this edition, experience and, perhaps, the recent development of thoracic surgery have led to rearrangement and amplification of the section on the thorax.

Modern Clinical Psychiatry. By Arthur P. Noyes, M.D., Superintendent, Norristown State Hospital, Norristown, Pennsylvania. Fourth edition. Cloth. \$7. Pp. 609. W. B. Saunders Company, 218 W. Washington Sq., Philadelphia 5; W. B. Saunders Company, Ltd., 7 Grape Street, Shaftesbury Avenue, London, W.C.2, 1953.

This new edition of what is possibly the best general textbook of psychiatry written and published in this country contains many sections that are revised and many that are completely new. There is a greater emphasis in this edition on psychological influences and motivations in the production of personality disorders. The principles of basic psychiatry are presented more fully, and the genetic and dynamic concepts are expanded. Although the author is not a psychoanalyst, he presents many of the most important currently accepted psychoanalytic concepts. The classification of mental disorders that is used is the standard nomenclature adopted by the American Psychiatric Association. An excellent bibliography is included at the end of every chapter. The book should be an invaluable textbook not only to psychiatrists but to physicians in other specialties, medical students, and persons in related fields such as nursing, social work, and psychology.

These book reviews have been prepared by competent authorities but do not represent the opinions of any official bodies unless specifically so stated.

QUERIES AND MINOR NOTES

DRUG TREATMENT OF PULMONARY TUBERCULOSIS

TO THE EDITOR:—*The chest roentgenogram of a 36-year-old patient shows a questionable tuberculous lesion in the right apex at the right front first interspace. In a 60-year-old patient the roentgenogram shows a partially calcified area in the second left front interspace. They have both been given dihydrostreptomycin for two months. Is it advisable to give isoniazid at the same time other therapy is used? What company makes isoniazid? What further therapy would you suggest in these cases?* M.D., Pennsylvania.

ANSWER:—The inquirer does not ask about the propriety of treating these patients. Since the diagnosis in one was "questionable" and the other had a "calcified area," there is a need for finding tubercle bacilli before launching into a long treatment involving not a few hazards. It is almost mandatory to be sure that an active tuberculous infection is present before good results can be expected.

As to proper method of treatment, streptomycin and dihydrostreptomycin are not given alone any more, since the bacilli soon develop resistance in about 80% of the cases. Until recently *p*-aminosalicylic acid was also given in 3 gm. doses four times a day. Now isoniazid can be given in doses of 3 to 4 mg. per kilogram of body weight in divided doses three to four times a day along with the streptomycin drugs. Isoniazid alone also tends to engender resistance in the bacilli. When given with the other drugs this resistance is about a third of that when the drugs are given alone.

Almost all the drug houses in the world are making isoniazid under their own trade names. Certainly every one of about two dozen drug houses in America is making it. Further therapy should be based on the clinical, x-ray, and laboratory findings in the respective cases. Control work is almost as essential as it is in diabetes. The prognosis under the circumstances cannot very well be given without more information. In addition to control of the bacilli and bacillary resistance, a rest regimen should be carried out for a period, with a gradual increase in exercise as the clinical conditions warrant.

RESORPTION OF EXCESS SUBCUTANEOUS FAT

TO THE EDITOR:—*I would like information on the hastening of resorption of excessive subcutaneous deposits of fatty tissue. Elman has reported the rapid absorption of 5% protein (Amigen) after subcutaneous deposit by clysis, with the aid of hyaluronidase. Shafroff reports similar results with the subcutaneous clysis of 10% fat emulsion, with the aid of the enzyme, without side-effects and without a residue of fat remaining at the clysis site. Elsewhere, methods taken presurgically in vital staining of lymph nodes and channels in cancer surgery demonstrate the clear delineation of such channels by dye plus hyaluronidase. Is it rational to use exercise and manual massage to break down the cellular structure of the fatty deposit, to follow this with injection of the area with the enzyme, and to expect a more rapid absorption of such fat deposits?* M.D., California.

ANSWER:—Two questions have been propounded, one of them dealing with the use of exercise and massage to break down the cellular structure of subcutaneous fat. The answer to this question can be found in a communication by Frank H. Krusen in *THE JOURNAL*, Jan. 24, 1953, page 296. Two quotations may be cited from this communication: "There is

no scientific proof whatever that massage of any type can be effective as a reducing measure," and ". . . the value of nearly all of these devices (for 'spot reducing') is absolutely nil. . . ." In regard to the second question, hyaluronidase is really a spreading agent, and there is little or no evidence that it increases the absorption from the subcutaneous tissues of any fluid except isotonic sodium chloride solution.

INTRAPERITONEAL ADMINISTRATION OF SALINE SOLUTION

TO THE EDITOR:—*When it is difficult in children to give normal saline solution intramuscularly, rapidly, and in sufficient amounts, is it rational to give it intraperitoneally?*

H. E. Dester, M.D., Jagdeeshpur, India.

ANSWER:—Intraperitoneal injection of selected fluids has its advocates and is rational. If large amounts of parenterally administered fluid are desired and other routes are not available, or in the situation cited, isotonic sodium chloride solution is well tolerated intraperitoneally. This route should not be used if abdominal distention, peritonitis, or dyspnea from pneumonia exists, nor within 12 hours of laparotomy. In dehydrated infants and children, from 60 to 100 cc. of isotonic sodium chloride solution per kilogram of body weight may be given in from 15 to 20 minutes and be quickly absorbed, if the contraindications mentioned do not exist.

INTOLERANCE TO IRON THERAPY

TO THE EDITOR:—*Please outline the treatment of patients with anemia who require iron but who manifest various degrees of intolerance. My patient becomes ill, with nervousness, malaise, and irritability, regardless of what type of iron is given or whether it is given orally, intravenously, or subcutaneously.*

Lloyd R. Hennig, M.D., Willows, Calif.

ANSWER:—Inability to tolerate iron is a rare but occasionally encountered problem in the management of iron-deficiency anemia. Ferric cacodylate given intravenously is occasionally tolerated when ingested iron is not. If this has been tried unsuccessfully, it is probably best to resort to the use of a diet high in protein and iron content and to correct, as far as possible, such contributing factors as loss of blood, vitamin deficiency, a deficiency of thyroid secretion, and chronic infection. The diet should contain generous supplies of muscle meat and liver, leafy green vegetables, whole grain cereals, and possibly molasses and raisins. Supplements of amino acids may be desirable.

THE AUSCULTATORY GAP

TO THE EDITOR:—*In Queries and Minor Notes in THE JOURNAL, Aug. 15, 1953, a correspondent, referring to the auscultatory gap in blood pressure readings, stated that he had seen only one case in 25 years. In my experience the phenomenon is extremely common. It is easy to avoid missing it. The upper limit of systolic pressure is first estimated by inflating the cuff with a finger on the radial pulse and is then checked with the stethoscope. In cases in which an auscultatory gap occurs there is no coincident disappearance of the pulse.* John Dardess, M.D., Chatham, N. Y.

CORRECTION

Actinic Dermatitis.—In the query entitled "Actinic Dermatitis," in *THE JOURNAL*, Nov. 28, 1953, page 1232, the term "*p*-aminosalicylic acid" in the fifth line of the answer was erroneous and should have been "*p*-aminobenzoic acid."

The answers here published have been prepared by competent authorities. They do not, however, represent the opinions of any official bodies unless specifically so stated in the reply. Anonymous communications and queries on postal cards cannot be answered. Every letter must contain the writer's name and address, but these will be omitted on request.

PANCREATIC CONSIDERATIONS IN GASTRIC SURGERY

Kenneth W. Warren, M.D., Boston

Gastric surgeons have long been wary of injuries to the pancreas during the mobilization of certain benign and malignant ulcers of the stomach or duodenum. Failure to respect the possibilities of injury to the pancreas under such circumstances is an invitation to disaster. Surgeons are less aware, however, of the occurrence of varying degrees of pancreatitis or fulminating pancreatic necrosis following gastric surgery. Schmieden and Sebening¹ pointed out many years ago that acute pancreatitis as a complication of surgery on organs adjacent to the pancreas was commoner following operations on the stomach than on any other viscera (table 1). The traditional concept that pancreatic affections related to gastric or duodenal surgery were always secondary to trauma cannot, in our opinion,² be sustained by a careful analysis of the pertinent data. Millbourn,³ in an excellent survey of this problem, considered many etiological factors and implied that his own material at least could be fitted into a broad etiological pattern. Pancreatic affections following gastric surgery are unpredictable. They occur in some patients in whom the anatomic relationships are normal, when the technical requirements are routine, and without obvious injury to the pancreas. The experience of Dunphy, Brooks, and Achroyd⁴ is comparable to ours in the respect that these authors could not relate the cause of the pancreatic complications to a rigid etiological pattern.

In addition to injuries to the pancreas and to post-operative pancreatitis after gastric and duodenal surgery, recent interest has been manifest in the role that the pancreas may play in the nutritional status of the patient who has undergone gastrectomy. Pancreatic anomalies occasionally cause gastroduodenal symptoms and confuse the differential diagnostic picture as viewed roentgenographically. It seems pertinent, therefore, to consider in a single communication the problems of pancreatic injury, pancreatic anomalies, acute pancreatitis, and pancreatic physiology as these conditions relate to the nutritional status of the patient who has undergone a gastric operation.

INCIDENCE OF PANCREATIC COMPLICATIONS

Although it would be misleading to imply that pancreatic injuries, acute pancreatitis, or major disturbance in pancreatic physiology are common after gastric resection, it is undoubtedly true that such complications are commoner after gastric surgery than has been realized. Since the diagnosis will be missed, particularly in the mild cases, unless the condition is suspected and specifically searched for, and since the diagnosis will also be missed in many instances unless a postmortem examination is performed in the fatal cases, one may surmise that the reported cases represent but a small percentage of the total incidence. Reliable data in this regard will be available only when a significantly large consecutive group of patients subjected to gastric operations has been studied routinely for disturbances in diastatic activity in the early postoperative state. Usland⁵ and Block⁶ found that only an occasional patient showed elevation of the serum diastase preoperatively even in the presence of ulcers penetrating into the pancreas. Usland found a significant elevation of diastatic activity in the urine postoperatively in 13%, or 24 cases, of gastric resections for ulcer. Millbourn emphasized that elevation of the urinary diastase was four times as common after gastric resection for duodenal ulcer as for gastric ulcer or carcinoma. We have recognized seven cases of acute pancreatic necrosis complicating gastric surgery during the four year period from 1949 through 1952. During that time there were 499 gastric resections performed for duodenal ulcer, 203 for gastric ulcer, and 190 for carcinoma of the stomach, indicating that the recognized incidence of this complication is uncommon. It is significant, however, that pancreatic affections constituted one of the commonest causes of death after gastric operations during that interval. This observation implies that, as other serious complications that historically accounted for the major part of the mortality of gastric surgery have gradually been reduced or eliminated, the prevention and control of pancreatic affections related to gastric surgery constitute one of the most serious hazards with which we currently must contend.

From the Department of Surgery, the Lahey Clinic.

Owing to lack of space, the bibliographic references have been omitted from THE JOURNAL and will appear in the author's reprints. Read before the Section on Surgery, General and Abdominal, at the 102nd Annual Meeting of the American Medical Association, New York, June 2, 1953.

ously, but the jejunal fistula required secondary resection. In the third case in which pancreatic injury occurred at the clinic, both the common bile duct and the duct of Wirsung were divided during the mobilization of a low-lying posterior penetrating duodenal ulcer. This injury was recognized immediately and the type of repair employed has been previously reported by Lahey.⁹ In the three cases of pancreatic injury in operations performed elsewhere the duct of Wirsung alone was divided in one instance and in the other two patients the duct of Wirsung and the common bile duct were both divided. We have, of course, observed injuries to the tail of the pancreas during total gastrectomy. These injuries occur during the mobilization and removal of the spleen. Such injuries are usually minor as compared with injuries to the pancreatic duct near the papillae, but occasionally they may invite a temporary fistula or, more commonly, a subphrenic abscess.

MANAGEMENT OF MAJOR INJURIES TO DUCT

Injuries to the duct of Wirsung in the region of the head or the tail of pancreas can be dealt with satisfactorily in most instances. In the presence of malignant

formed pancreas, the pancreatic fistula was permitted to close spontaneously. In the remaining cases the following types of repair were performed. The patient with division of the duct of Wirsung without involvement of the common bile duct had the duct of Wirsung anastomosed to the duodenal stump five months after the initial operation performed elsewhere. In one instance the divided end of the common duct was sutured to the duct of Santorini and a cholecystojejunostomy was performed. One patient had had a cholecystojejunostomy elsewhere that relieved the biliary fistula, but the persistent pancreatic fistula arising from the transected duct of Wirsung was treated by anastomosing the duct to the duodenal stump. In one instance in which both the common bile and the main pancreatic ducts had been divided elsewhere, repair was effected by implanting each duct into the mobilized duodenum. In one case in which injury to the common bile and main pancreatic ducts was recognized immediately, repair was accomplished by implantation of the ducts into the jejunum.

Attempts to eliminate persistent pancreatic fistula, resulting from complete division of the duct of Wirsung near the ampulla, by cauterization, x-radiation, and

TABLE 2.—Pancreatic Injury During Gastrectomy

Case	Age, Yr.	Diagnosis	Nature of Injury	Place of Original Operation	Type of Reconstruction	Results and Length of Follow-Up
1	40	Duodenal ulcer	Division of common bile and main pancreatic ducts	Clinic	Implantation of ducts into jejunum	Excellent; 9 yr.
2	66	Duodenal ulcer perforating into common bile duct	Division of common bile and duct of Santorini	Clinic	End of common duct sutured to duct of Santorini; cholecystojejunostomy	Excellent; 6 yr.
3	52	Duodenal ulcer	Division of duct of Wirsung	Elsewhere	Duct anastomosed to duodenal stump 5 months after initial operation	Excellent; 4 yr.
4	25	Duodenal ulcer	Division of duct of Wirsung and common bile duct	Elsewhere	Both ducts implanted into mobilized duodenum	Excellent; 2 yr.
5	46	Duodenal ulcer	Division of common bile and pancreatic ducts	Elsewhere	Cholecystojejunostomy elsewhere; pancreatic fistula persisted; duct of Wirsung anastomosed to duodenum	Excellent; 4 mo.
6	37	Duodenal ulcer, annular pancreas	Division of minor pancreatic duct during excision of annulus	Clinic	Pancreatic fistula closed spontaneously; jejunal fistula resected	Excellent; 1 yr.

lesions that involve the pancreas secondarily, injuries to the major duct in the body or the tail of the gland are best treated by distal pancreatectomy and by careful closure of the stump of the pancreas with silk mattress sutures. Injuries to the periampullary portions of the pancreatic ducts can be extremely serious, and their proper management requires more judgment, skill, and ingenuity. Millbourn has stressed the necessity of demonstrating a functional connection between the duct of Santorini and the main pancreatic duct if division of the duct of Santorini is to be treated by simple ligation. This may be done, as he suggested, by injecting a colored solution into the severed end of the duct and watching for the return of the solution into the duodenum through the papillae of Vater, or pancreato-angiography may be preferred. If the duct of Santorini does not communicate with the duct of Wirsung it will be necessary to implant the duct of Santorini into the duodenum or jejunum. Injuries to the duct of Wirsung within the head of the pancreas will usually be associated with injuries to the common bile duct and will require implantation of each duct into the duodenum or jejunum. At the clinic in one case in which a pancreatic fistula followed excision of the annular portion of a mal-

sclerosing solutions not only will fail but may actually do further harm to the pancreas. Implantation of the fistulous tract into segments of the upper gastrointestinal tract will also fail in most instances because of secondary stricture of the fistulous tract. The necessary requirement for a satisfactory result is careful approximation of the duct itself to the duodenum or jejunum. This can be accomplished by following the fistulous tract down to the pancreas and then by identifying precisely the epithelial lining of the pancreatic duct.

RESULTS OF REPAIR OF INJURY TO DUCTS

In the five patients who have had repair of pancreatic ducts following injury resulting from gastroduodenal surgery the results have been excellent in terms of eliminating pancreatic fistula and also in terms of preventing secondary stenosis and interference with pancreatic function. One patient, case 2 in table 2, who had an injury to the duct of Santorini did have a spontaneous recurrence of a pancreatic fistula 18 months later, following prolonged excessive consumption of alcohol. The patient was brought to the hospital and placed on a careful dietary routine, the fistula closed completely, and the pa-

tient has remained well and has followed his dietary restrictions carefully. One patient, case 1 in table 2, has had some recurrent gastrointestinal symptoms nine years after the implantation of the common bile and main pancreatic ducts into the jejunum, and it is possible that he may have a jejunal ulcer, although this cannot be definitely proved.

The real tragedies resulting from injuries to the major pancreatic ducts during gastric surgery derive from failure to recognize and to correct these injuries rather than from their irreparable character. The *sine qua non* of successful management of injuries to the major pancreatic ducts, whether they be repaired immediately or after a persistent fistula has occurred, is careful approximation of the severed duct to some segment of the upper gastrointestinal tract. The epithelium of the duct must be sutured carefully to the mucosa of the intestinal tract.

ACUTE PANCREATITIS FOLLOWING GASTRIC RESECTION

In attempting to discern some common etiological factor or factors in the production of acute pancreatitis following gastric surgery we have selected seven cases from

was done. Although there had been no surgical manipulation of the duodenum, extensive pancreatic necrosis developed from which the patient died on the ninth postoperative day. Postmortem examination revealed diffuse pancreatic necrosis and an active penetrating duodenal ulcer in the first part of the duodenum. In another instance the mobilization of the ulcer was not particularly difficult and there was much less pancreatic involvement than is frequently seen in such cases at the time of operation, yet fatal pancreatitis ensued. In one case the operation was performed for an obstructing duodenal ulcer in which no penetration was found. The technical procedure in this instance was not involved, and no undue manipulation of the pancreas was required (case 2, table 3). The pancreatic necrosis was extensive in this instance and resulted in death on the ninth postoperative day. These facts are in harmony with those previously referred to in the literature, which indicate that this complication may occur even after simple gastroenterostomy. Finally, case 7 in table 3 demonstrates that acute pancreatitis may occur following gastrectomy (total gas-

TABLE 3.—Acute Pancreatitis Following Gastric Resection

Case	Age, Yr.	Diagnosis	Operation	Time of Onset of Postoperative Symptoms	Result	Results of Post Mortem
1	36	Penetrating duodenal ulcer; repeated hemorrhages; duodenum not manipulated	Reresection; patient had previous resection elsewhere	2d day	Died 9th day	Extensive pancreatic necrosis
2	48	Obstructing duodenal ulcer; previous hemorrhage	Partial gastrectomy	24 hr.	Died 9th day	Extensive pancreatic necrosis
3	35	Nonpenetrating ulcer	Partial gastrectomy	24 hr.	Died 28th day	Extensive pancreatic necrosis
4	50	Penetrating duodenal ulcer	Partial gastrectomy	24 hr.	Died 5th day	Marked pancreatic necrosis in head; duct of Wirsung drained only small part of head of pancreas; duct of Santorini not identified but apparently was main pancreatic duct
5	44	Penetrating duodenal ulcer	Partial gastrectomy	24 hr.; then subsided; recurred 19th p. o. day	Died 19th day	Massive diffuse pancreatic necrosis
6	52	Penetrating duodenal ulcer	Partial gastrectomy	24 hr.	Died 9th day	Pancreatic necrosis
7	65	Carcinoma of cardia	Total gastrectomy; splenectomy	24 hr.	Recovered; permanent diabetic	

the files of the Lahey Clinic in which the diagnosis of pancreatic necrosis was obvious. In addition to these cases we have observed other instances of less severe involvement in which recovery occurred, but these seven cases point up the main problems referable to this complication and constitute some revealing as well as some confusing clinical data. It will be noted that four of the seven patients (table 3) had penetrating duodenal ulcers, and one had carcinoma involving the cardia. Although this factor of penetration might at first appear decisive, it must be borne in mind that most duodenal ulcers that are resected at the clinic are posterior penetrating ulcers and that the incidence of this complication is quite small. Another observation that questions the importance of this factor of penetration in the etiology of pancreatitis following gastrectomy is demonstrable by case 1, table 3, in which instance a previous gastric resection had been performed elsewhere and the patient was operated on again here because of repeated hemorrhage. At the second operation the duodenal stump was examined but not manipulated, but, since the patient had had a limited resection at the original operation, a more radical resection

trectomy in this instance), even when the malignant lesion does not directly involve the pancreatic substance. It is possible, of course, that such pancreatic involvement may be secondary to injury of the tail of the pancreas resulting from mobilization of the spleen, but in this instance the clinical course was suggestive of pancreatic necrosis rather than of pancreatic extravasation, and this presumption is supported by the fact that acute diabetes developed during the attack and that the diabetes was permanent. Another significant and confusing factor in attempting to specify the cause of these complications is the demonstration that the areas of pancreatic necrosis are not necessarily confined to the head, and, indeed, areas of pancreatic necrosis may occur in the body or tail of the gland when the head of the pancreas appears normal.

Recognition.—Our initial interest in this subject resulted from the observation that an occasional complication following gastric surgery had the clinical appearance of acute pancreatic necrosis. Subsequent events confirmed this suspicion. The most characteristic clinical feature of these patients with severe pancreatic necrosis

following gastric resection is the violence of the onset of abdominal symptoms in the immediate postoperative period. It may be observed in table 3 that the symptoms of pancreatic complications appeared in six of the seven cases within 24 hours after the operation and that in the seventh case the postoperative symptoms were apparent in 48 hours. The violence of the abdominal pain, the reference to the back, its persistent, unyielding quality, and its tendency to be associated with peripheral vascular collapse are extremely suggestive and should afford recognition of this complication. The demonstration of tenderness in the flanks and the subsequent appearance of edema in the flanks, and in some instances of Grey-Turner's sign, will confirm the diagnosis. The appearance of jaundice, which occurs in about 75% of these patients, may be due to obstruction of the bile duct by swelling and induration of the head of the pancreas or to a toxic hepatitis.

To suspect the pancreatic complication is to recognize it, because significant elevation of serum or urinary amylase can always be demonstrated if the determination is made within 24 to 48 hours after onset of the symptoms. Because of our particular interest in this problem, it is routine at the clinic to regard almost every case of intra-abdominal complication in the period immediately following gastric surgery to be of pancreatic origin until proved otherwise.

Secondary operations were performed in two cases. In one instance bilateral incisions were made and drainage of the retroperitoneal space was performed through the separate incisions in each flank. Considerable necrotic debris was evacuated, but the patient died on the 28th postoperative day. In another instance the patient showed initial signs of pancreatic involvement that subsided but recurred violently on the 19th day, at which time a small incision was made in the right upper abdominal quadrant. Considerable hemorrhagic fluid was obtained, but the patient went into profound collapse and died within a short time. Autopsy revealed massive, diffuse pancreatic necrosis.

The mortality in this selected group was extremely high, there being six deaths in the seven cases (85.7%), but these cases were selected because of the extreme degree of the complication and because the diagnosis could be substantiated in every instance.

The autopsy findings were fairly consistent in five of the six fatal cases in which postmortem examination was permitted. In one case (case 4, table 3) marked pancreatic necrosis was present in the head of the gland. The duct of Wirsung drained only a small portion of the head of the pancreas, while the duct of Santorini, which was not identified, apparently constituted the main pancreatic duct. This may be an instance in which fatal pancreatitis resulted from injury to the duct of Santorini, although no such injury was demonstrable at post mortem. The other four patients showed severe pancreatic necrosis, and in one instance the areas of necrosis were patchy, with the body and tail being more involved than the head.

Treatment.—Prevention of pancreatic inflammation and necrosis following gastric resection may be difficult in view of the fact that the precise cause is not known. It is plausible, however, to assume that the large, penetrat-

ing, acutely inflamed, posterior duodenal ulcer is more likely to invite a pancreatic complication than are other types of duodenal ulcers. It is wise, therefore, to evaluate carefully and precisely the possibilities of injury to the pancreas and to consider the likelihood of pancreatic inflammation following resection of such an ulcer before mobilization of the stomach is attempted. When faced with such an ulcer one has the alternatives of performing: (1) a pyloric exclusion as advocated by Finsterer,¹⁰ (2) the two stage resection as advocated by McKittrick and his associates,¹¹ which in their hands has proved to be safer in this type of ulcer than has been the one stage operation, and (3) gastroenterostomy and vagotomy. Pyloric exclusion in our experience has given the highest incidence of recurrent ulcer activity and is rarely employed in this clinic. The objections to the two stage resection advocated by McKittrick include the double jeopardy of two anesthetics, two operative maneuvers, and two periods of recumbency and the possibility that the patient will be left with an inadequate operation if he refuses to go through the second stage.

It is a general principle here at the clinic to perform partial gastric resection in practically all cases of duodenal or gastric ulcers subjected to surgery. In most of these instances the ulcer is completely removed. In some instances, however, when the ulcer is low-lying, it is possible to remove the entire stomach and pylorus and to invert the first part of the duodenum above the ulcer. This leaves very few cases in which one of these three alternatives must be employed, and it is our belief at present that, when one is faced with the possibility of pancreatic injury or an invitation to pancreatic inflammation in the acutely inflamed posterior duodenal ulcer, it is preferable to do a gastroenterostomy and vagotomy. If resection is resorted to, the mobilization of the duodenum must be done with care. The penetration into the pancreas should not be excised, covered, or curetted. Any large structure traversing the groove between the head of the pancreas and the posterior wall of the duodenum should be aspirated to rule out the possibility that it is the pancreatic duct before clamps are applied. It is difficult for anyone to speak with authority relative to the treatment of postoperative pancreatitis for, by necessity, one's experience is limited, and if we may judge by the meager literature relative to this affection following major surgery, the mortality in series of proved cases is universally high. There is little doubt, however, that the treatment should be similar to that of primary pancreatitis, which today is generally agreed to be conservative nonoperative management. One is struck by the fact that those patients who have secondary laparotomy usually pursue a rapidly fatal course. This management should include: (1) continuous gastric suction to minimize distention; (2) control of pain by meperidine (Demerol) in milder cases and by continuous epidural procaine analgesia (Orr and Warren¹²) in those instances in which the pain is unresponsive to administration of narcotics; (3) maintenance of circulating blood volume by adequate amounts of serum albumin and appropriate quantities of glucose-electrolyte solutions; (4) detection and control of acute diabetes and hypocalcemia; (5) use of penicillin and/or chlortetracycline (Aureomycin); and (6) drainage of secondary septic

collections. If one feels compelled to attempt drainage of the pancreatic bed during the acute attack, one would do well to consider the unilateral or bilateral flank approach, particularly in those instances in which brawny induration and edema are demonstrable in these areas. The lumbar approach can be pursued with less anesthesia and without any intraperitoneal manipulation.

RELATIONSHIP OF PANCREATIC ANOMALIES
TO GASTRODUODENAL SURGERY

Aberrant pancreatic tissue located in the wall of the stomach or duodenum assumes practical clinical significance since these ectopic pancreatic masses may produce motor disturbances, ulceration, or secondary inflammatory reactions, and more particularly because their presence will frequently produce filling defects that are confused with gastric or duodenal polyps, ulcers, or malignant tumors. Since these pancreatic heterotopias are prone to occur in or around the pylorus, it is fre-

the ectopic mass had a central depression, representing the ductal opening into the stomach, which was thought at the time of abdominal exploration to be central necrosis in a gastric tumor. In two of the seven cases the aberrant pancreatic tissue was found incidentally at the time of operation for gastric ulcer. Gastric resection was performed in six of the seven cases, since frank ulceration was present in four and associated gastritis was present in two.

ANNULAR PANCREAS

Annular pancreas is a rare anatomic anomaly, but the frequency with which its presence is associated with secondary duodenal ulceration, particularly in the adult, and the infrequency with which the correct diagnosis is made either clinically or during abdominal exploration for suspected gastroduodenal disease point up the need for greater awareness of the clinical, roentgenologic, and surgical features of this malformation. The symptoms

TABLE 4.—Treatment of Aberrant Pancreas in Stomach or Duodenum*†

Case	Age, Yr.	Sex	Associated Pathological Condition	Duration of Symptoms	Operation	Location

TABLE 5.—Treatment of Annular Pancreas*

Case	Age, Yr.	Sex	Duration of Symptoms, Yr.	Operation	Complications	Results
1	37	M	18	Excision of annulus; partial gastrectomy	Pancreatic and jejunal fistula	Closure jejunal fistula; pancreatic fistula closed spontaneously
2	28	F	12	Pyloric exclusion (elsewhere); excision of antrum and first portion of duodenum	Pancreatic deficiency	Chronic malnutrition
3	41	F	15	Gastroenterostomy and vagotomy	None	Excellent

* In all three cases there was an associated duodenal ulcer.

quently necessary to operate on them, since the possibility of an existing malignant lesion cannot, with assurance, be ruled out. Ulceration with hemorrhage or pyloric obstruction also may indicate the necessity for surgical intervention. It is important, therefore, to consider the possibility of an ectopic pancreas in assessing any bizarre roentgen manifestation or operative finding in the region of the pylorus. If such an anomaly is suspected, the tumor should be excised locally, if feasible, and be submitted to immediate frozen section analysis.

Marshall and Curtiss¹³ have recently reported from this clinic seven instances of ectopic pancreas, five involving the stomach and two in which the aberrant pancreas was attached to the duodenum, which were associated with sufficient symptoms to warrant surgery. These cases are tabulated in table 4, from which it will be seen that in five of the seven cases the aberrant pancreas was the primary gastric disease and that superficial ulceration over the tumor was present in two of these five cases. Two other patients had local gastritis in the region of the pancreatic mass. In the fifth instance

vary in proportion to the degree of duodenal obstruction produced by the anomaly. If no compression of the duodenum is present there are no symptoms. Clinical manifestations include bouts of abdominal colic associated with nausea and vomiting. Failure to discern the correct diagnosis frequently leads to unnecessary and unavailing operations on the biliary tract and ultimately to a diagnosis of psychoneurosis.

When symptoms are present from birth, which usually indicates the presence of severe duodenal obstruction, early surgical intervention is carried out and the nature of the anomaly is usually recognized. When the symptoms are delayed and when they are less acute, chronic duodenal stasis may occur and lead to duodenal ulceration. Roentgen studies under such circumstances usually show the ulcer, but the primary pancreatic deformity is commonly missed. The deformity is generally characterized by a smooth band-like constriction of the descending limb of the duodenum, with dilatation of the proximal duodenal segment. Occasionally, a fine string of barium delineates the narrowed portion of the duo-

denum. Medial notching of the duodenal deformity, as stressed by Lehman,¹⁴ who is the only one who has recognized the lesion preoperatively, has not been observed by us.

We have operated on three patients with annular pancreas (table 5). All three were adults; symptoms had been present for 12, 15, and 18 years. Two patients had been operated on previously without the true nature of the pathological condition being perceived. One had had a cholecystectomy for noncalculous gallbladder, and one had had a pyloric exclusion. All three had duodenal ulceration.

Gastrojejunostomy and vagotomy were performed in one case, with good results. The retained pyloric antrum was excised in the patient who had had a previous exclusion operation. This patient had chronic pancreatic deficiency with severe malnutrition. The annulus was excised and a partial gastrectomy was performed in one patient. Pancreatic and jejunal fistula occurred. The pancreatic fistula healed spontaneously, but the jejunal fistula required operative closure. This patient subsequently did well.

The treatment of choice in annular pancreas in the absence of chronic duodenitis or duodenal ulcer is duodenojejunostomy. If the first part of the duodenum is scarred or ulcerated, it is perhaps wise to employ gastrojejunostomy with vagotomy. The annulus should not be resected, in my opinion, because of the likelihood of a pancreatic fistula, the possibility of injury to the major pancreatic duct, and because resection of the annulus may not relieve the duodenal atresia that is associated.

ROLE OF PANCREAS IN POSTGASTRECTOMY NUTRITIONAL PROBLEMS

Some impairment in the digestion and absorption of food after gastroenterostomy, partial gastrectomy, or total gastrectomy is frequently observed. This deficiency may be reflected in a failure to regain normal weight, difficulty in maintaining postoperative weight, and the presence of excessive quantities of fat and, less commonly, protein in the stools. Factors contributing to this impairment of nutrition include: (1) diminution in intake of food; (2) the entrance of larger food particles into the intestine, which makes it more difficult for the bile and the pancreatic and intestinal ferments to act on the food substances; (3) more rapid passage of food through the gastrointestinal tract; and (4) a diminution in external pancreatic secretion. This last impairment is usually least marked in gastroenterostomy and most profound following total gastrectomy. Despite the voluminous literature relative to the difficulties in maintaining nutrition in the patient who has undergone gastrectomy and especially in the patient who has been subjected to total gastrectomy, it has been our experience at the clinic that very little difficulty will be encountered in the patient who has had gastroenterostomy, with or without vagotomy, or partial gastrectomy and that the difficulties that are encountered in patients who have had total gastrectomy are rarely extreme except in those patients who have recurrent or persistent malignant disease.

Wollaeger¹⁵ found that after partial gastrectomy in man fat absorption was slightly better when the Billroth 1 type of anastomosis was done, as compared with a Polya type of restoration. After total gastrectomy in dogs Everson¹⁶ found that the type of anastomosis had little or no effect on absorption of fat but that, in animals in which an esophagoduodenal anastomosis was performed, the loss of nitrogen in the feces was less than in those dogs that had esophagojejunal anastomosis. It can readily be demonstrated, as shown by Howard and his associates,¹⁷ that the rate of external pancreatic secretion is diminished when a test meal is delivered to the jejunum approximately 2 ft. (61 cm.) beyond Treitz's muscle as compared with the delivery of the same test meal into the duodenum or given orally. In most of the conventional types of gastrojejunostomy following gastric resection, however, the gastrojejunostomy is sufficiently close to Treitz's muscle to permit reflux of food into the duodenum in such a way as not to impair pancreatic function.

A variety of agents has been employed in an effort to increase the absorption of fat after gastrectomy. These include bile, pancreatin, emulsifiers, hydrochloric acid, and vitamins, particularly folic acid. Emery¹⁸ has shown in dogs, as have Brain and Stammers¹⁹ in man, that fat absorption can best be increased after total gastric resection by the use of small, frequent feedings.

These experiences parallel those of persons in our own department of gastroenterology, who have for many years insisted that most nutritional problems following partial or total gastrectomy can be controlled by small, frequent feedings of carefully selected articles of diet. The validity of this contention is best exemplified by the fact that of 15 patients subjected to total gastrectomy for benign lesions only one has presented any significant nutritional problem. This one patient has had difficulty in maintaining his weight, although his blood cell counts are normal and his energy is such that he is able to work regularly even though he is beyond 70 years of age. We have also demonstrated in this patient that by careful, frequent feedings under hospital control he is able to gain as much as 5 lb. (2.3 kg.) in three weeks. In the light of a large experience with both partial and total gastric resection here at the clinic, we believe that the problem of postoperative nutrition in this group is not essentially one of major impairment in digestion or absorption of food and that such nutritional problems can largely be avoided by determining that the patients get an adequate caloric intake. This usually means frequent small meals in those persons who tend to have any nutritional deficiency. Again, in the light of this experience, we have not been tempted to resort to the Billroth 1 type of procedure nor have we felt constrained to employ any transposition of a segment of the gastrointestinal tract as an artificial stomach after total gastrectomy. Although it is undoubtedly true that minor disturbances in pancreatic function occur as a result of radical subtotal or total gastric resection, these deficiencies apparently do not occur commonly and when they do are not severe.

NUTRITION AFTER GASTRIC OPERATIONS

Robert M. Zollinger, M.D.

and

Edwin H. Ellison, M.D., Columbus, Ohio

A significant number of gastric operations result in rather distressing postoperative complaints that are unrelated to the original pathology and probably are referable to the surgical procedure.¹ Although the loss of a part or all of the stomach may seem a small price to pay to avoid the consequences of recurrent ulcer or fatal neoplasm, a significant number of patients manifest subsequent nutritional deficiencies that may be severe enough to prove incapacitating to the occasional patient.² During the past three and one-half years a study has been undertaken in an attempt to gain further information regarding the incidence, etiology, management, and possibly the prevention of nutritional problems following gastric surgery.

Physicians responsible for the late postoperative care of patients with gastric surgery have long been impressed by the problems they present. Diminished appetite, limited food capacity, frequent discomfort after meals, high incidence of food idiosyncrasy, and occasional diarrhea may result in a significant weight loss or the inability to gain weight.³ At times these sequelae prevent these patients from making adequate social and economic adjustments.⁴ Observations on the postoperative nutritional status of 203 unselected ulcer patients subjected to a variety of standard surgical procedures suggest that preoperative weight should be an important consideration in planning the type of gastric surgery, especially for duodenal ulcer.

INCIDENCE OF WEIGHT DEFICIENCIES

The nutritional status of the group studied one to six years after gastric surgery has been determined by examination and interviews. Three out of every four have been seen more than once; of these, one-half have been interviewed at yearly intervals for at least three years.

The youngest patient reported on was 20 years old and the eldest was 75; the average age was 52 years. There were 162 men and 41 women. The operative and/or pathological diagnosis was duodenal ulcer in 163 cases. In the remainder, there were 27 cases of benign gastric ulcer, 10 of gastrojejunal ulcer, and 3 of duodenal and gastric ulcers occurring together. For purposes of simplicity, those patients with marginal ulcerations or combined duodenal and gastric lesions were classified in the duodenal ulcer group, giving a total of 176.

Records of weight gain or loss one to six years following operation were used as an index of the state of nutrition. Over one-half, or 109 of the 203 patients, failed to regain their preoperative weight; furthermore, a total of only 16 patients reached their maximum preoperative weight.

Of more significance is that the postoperative body weight was found to be below the minimal ideal standards⁵ for the sex, age, height, and body build in 127 of the total cases (table 1). In some instances, this weight deficit was considerable and exceeded 10% of

the minimal ideal weight in nearly one out of every three patients. The minimal ideal weight is 5 lb. (2.3 kg.) less than the average as defined by insurance weight tables.⁵ For example, the average ideal weight for a 5 ft., 8 in. (170 cm.) 40-year-old man of medium build is 152 lb. (69.1 kg.), and his minimal ideal weight is 147 lb. (66.8 kg.). From a consideration of this data it is apparent that the majority of these patients postoperatively were on the lean side, since the weight of 62% of the total group fell below minimal ideal standards.

POSTOPERATIVE WEIGHT TRENDS IN DUODENAL ULCER PATIENTS

Subtotal gastric resections were performed in 132 of the 176 duodenal ulcer patients; the Hofmeister-Polya technique was used in 101, and, of these, 27 had the additional procedure of vagotomy (table 2). The remaining 31 resections were of the Billroth 1 type combined with vagotomy. The resection in the Hofmeister-Polya group was of the conventional 75% type, with division of the left gastric artery close to its origin. When vagotomy was added to this type of procedure, the amount of resection remained at 75% in 18 of the 27 and was decreased to 40% in the remaining nine. In the Billroth 1 and vagotomy group, resection averaged between 60 and 65%. Vagotomy with gastroenterostomy accounted for the remaining 44 duodenal ulcer patients.

The body weight at follow-up examination was found below the minimal ideal in almost two-thirds (62%) of this group of 176 (table 1). This weight deficit was considerable in nearly one out of every four patients, exceeding 10% of the minimal ideal weight. Further analysis of these deficits demonstrated definite relationships to the type of operation performed.

About two-thirds of the patients having Hofmeister-Polya type resections with or without vagotomy failed to attain their minimal ideal weight after operation (table 1). Considerable improvement was noted in the vagotomy-gastroenterostomy series, in which 40% failed

to meet the minimal weight standards; and the best nutrition was found in the Billroth 1 combined with vagotomy group, in which only 33% fell short of the minimal weight standards.

An analysis was then carried out to determine whether or not the nutritional trends following gastric surgery might have been foretold by a consideration of the weight status before operation. As a result of this analysis, the patients fell into three major categories, depending on their weight at the time of operation and the relationship of this weight to the calculated minimal ideal standard. Group 1 included those patients whose preoperative weight was ideal or above; group 2 those who had realized their ideal weight sometime in the past, but whose weight at the time of operation was

TABLE 1.—Postoperative Procedures and Weight Trends of Patients Subjected to Gastric Surgery

Procedure	No. of Cases	Average Time After Surgery, Mo.	Follow-Up Weight Below Ideal, Lb.	No. with Ideal Weight Defect Greater Than 10%

Vagotomy with gastroenterostomy	36.0%	23.0%	13.0%	10.0%	33.0%

below their minimal standard; and finally, group 3, those who had never realized their ideal weight.

Thirty-one of the 74 patients studied after subtotal Hofmeister-Polya resections for duodenal ulcer were at their ideal weight or above (group 1) at the time of operation, and 21 of these were still above their minimal standard at follow-up—a two out of three chance of maintaining satisfactory nutrition. In direct contrast to this relatively good nutritional prognosis, only 3 of the 27 patients who fell into group 2 have been able to realize their ideal weight following operation—a one in 10 chance of meeting minimal weight standards. Finally, as might have been predicted, none of the 16 patients in group 3 realized their minimal ideal weight following gastric resection.

Similar observations were then made for each of the remaining surgical procedures employed, namely, major and minor Hofmeister-Polya resections with vagotomy, Billroth 1 resection with vagotomy, and vagotomy with gastroenterostomy. In each instance, the patients were

classified into three groups according to their preoperative nutritional status, and the percentage of patients reaching their minimal ideal weight was again determined. A comparison of the percentage of patients realizing this minimal standard following the various surgical procedures according to the preoperative nutritional category (groups 1, 2, and 3) permits a rough estimate of the long-term nutritional effects of the various gastric operations for ulcer.

In group 1 "best nutrition," as determined by the percentage of patients maintaining their ideal weight after operation, was noted following the 60% Billroth 1 resection with vagotomy. The number of patients maintaining their ideal weight following a limited 40% resection (Hofmeister-Polya technique) with vagotomy and following vagotomy with gastroenterostomy paralleled the incidence previously noted for the more extensive Hofmeister resection and averaged two out of three patients. In those few cases in which vagus section was combined with a 75% Hofmeister-Polya resection, only one out of six patients was able to maintain his ideal weight.

The improved nutrition following the Billroth 1 resection and vagotomy may not be of significance because of the small number of patients. The impression is gained that satisfactory weight trends may be expected in about two-thirds of those patients at or above their ideal weight at the time of operation regardless of the operative procedure if extensive resection of the Billroth 2 type combined with vagotomy is avoided.

The procedure of choice in group 2 was vagotomy combined with a 60% Billroth 1 resection or with posterior gastroenterostomy. Once again the best weight trends were realized following gastroduodenostomy, although the percentage difference was not great. Furthermore, the end results might well change with a larger number of cases and a more prolonged follow-up. Continued weight loss or inability to gain sufficient weight to meet minimal standards proved to be an almost universal problem following the more extensive resections either with or without vagotomy.

Sixteen of the 80 patients in group 2 fell below their ideal weight as a result of long-standing pyloric obstruction. Although we anticipated a good weight response in this particular group, only 10 had gained weight since the operation and, of these, only four had been able to meet their ideal weight. This tendency of a failure to gain weight in those patients with pyloric obstruction prior to surgery held true throughout the entire series in every group classification.

The nutritional effects of the various operative procedures in those patients who had never realized their minimal ideal weight preoperatively (group 3) were evaluated on the basis of the number of patients gaining weight after operation. In this instance, three out of four patients gained some weight following vagotomy combined with either gastroenterostomy or a 60% Billroth 1 resection, although "best nutrition," as indicated by the greatest average weight gain, occurred after vagotomy and gastroenterostomy. However, not a single patient in group 3 ever reached the minimal ideal weight following any type of procedure. Obviously a conservative type of operation seems clearly indicated in this group.

In summary, the preoperative weight of 65 of 176 patients with duodenal ulcer was equal to or over the minimal ideal weight (group 1), and of these, 43 were still above their ideal weight one to six years following operation. In contrast, only 23 of the 80 patients in group 2 and none of the remaining 31 patients in group 3 were able to reach their minimal standard weight following surgery.

POSTOPERATIVE WEIGHT TRENDS IN BENIGN GASTRIC ULCER PATIENTS

Twenty-two of 27 patients with benign gastric ulcer underwent radical gastric resections, and eight of these procedures were described as near-total resections. Intestinal continuity was established by gastrojejunostomy in 17 instances. The Billroth 1 technique was employed in the remaining 10 patients. No attempt was made to compare the end results of the three types of resection for this small series.

Weight trends following gastrectomy for gastric ulcer paralleled those of the entire group; however, the deficits were of greater magnitude. Seventeen of the 27 patients had lost weight since surgery, 22 were below their minimal ideal weight, and this deficit exceeded 10% in one out of every three patients. Decreased appetite, fullness, or discomfort after eating was noted in 15 patients, and it was these patients who had lost the greatest amount of weight. This increased weight loss and the frequency and severity of symptoms after meals is most likely explained on the amount of stomach removed.⁶ Unlike the situation in duodenal ulcer, the preoperative weight factor cannot be considered in planning the type of surgery, since the danger of malignancy makes radical resection necessary.⁷

COMMENT

A study of the postoperative weight trends in 203 patients one to six years after operation has appeared to show a definite relationship to their preoperative nutritional status. In our experience those patients whose preoperative weight was equal to or above their ideal weight showed the most consistent tendency to maintain a satisfactory weight after surgery. Slightly more than two-thirds of the patients in this group sustained a satisfactory postoperative weight regardless of whether a conservative procedure or a radical gastrectomy was performed. Seventy-four patients (36.4%) of the total series fell into this category.

In contrast to this satisfactory situation, the postoperative weight trends in the remainder of the patients in general were disappointing. The second group was made up of those who at the time of surgery were below ideal weights but who previously had weighed as much or more than ideal standards. In this group, composed of 94 patients, the number of patients who regained an ideal weight was reduced to slightly more than a third. It was here that the beneficial effect of the more conservative procedures became apparent (table 3).

Finally, in the third group, including those patients who had never attained their ideal weight, not a single patient attained this minimal ideal standard weight postoperatively. In this group were 35 patients, or 17.2% of the total. However, many of these patients did gain some weight, which was again directly related to the extent of

the surgical procedure. The best weight gains occurred in those patients having vagotomy and gastroenterostomy or in those with vagotomy combined with a 60% gastric resection and gastroduodenostomy. Throughout the entire series a radical gastrectomy of the Billroth 2 type combined with vagotomy had the most detrimental effect on postoperative weight trends.

The patient's preoperative weight in relationship to his ideal weight is an essential factor in planning the surgical management of duodenal ulcer. It is especially important in those patients whose weights are below the minimal ideal standard. It should be remembered that gastric surgery irrespective of type decreases the efficiency of fat and, in some instances, of protein absorption; although variable, this factor is most marked following extensive resections.⁸ In addition the caloric intake will be limited in many cases as a result of disagreeable symptoms after eating, the incidence of which seems to be greater following the more radical procedures.⁹

The preoperative weight of the patient should influence the surgeon in his selection of operation. While the

TABLE 3.—Nutrition After Gastric Surgery According to Weight

Operation	Ideal Weight Realized		Gained Some Weight, Group 3 (35)
	Group 1 (74)	Group 2 (94)	
For Duodenal Ulcer

Gastric resection	22.0% (2 of 9)	21.4% (3 of 14)	None

surgeon's preference may be utilized in those patients at or above ideal weight, he should strongly consider the more conservative procedure in those patients whose weight fails to meet these standards. We now tend to avoid the more extensive resections of the Billroth 2 type in groups 2 and 3. In these latter groups, we now utilize a 60% resection with a Billroth 1 type of anastomosis combined with vagotomy; when this procedure is not feasible technically, vagotomy and posterior gastroenterostomy are performed.

Finally, the surgeon has the responsibility of insuring a good nutritional status after gastric surgery. This may be accomplished by choosing an operation suitable to the patient's preoperative weight tendencies and also by paying close attention to the dietary management starting early in the postoperative period. To this end the use of seasoned, solid foods of minimal volume and low bulk and the avoidance of hypertonic fluids with meals have proved advantageous.

The wide divergence of reported results following gastric surgery for ulcer may well be explained by the varying nutritional states of the patients in the reported series. Perhaps the preoperative and postoperative weight trends and their relationships to ideal standards should be incorporated in the data used to evaluate the results of any surgical procedure.

SUMMARY AND CONCLUSIONS

Preoperative weight and the ideal weight are essential data in planning gastric surgery for duodenal ulcer. Satisfactory nutrition can be anticipated in two-thirds of patients who are at or above their ideal weight at the time of surgery, regardless of the procedure employed. Unsatisfactory weight trends should be anticipated in the great majority of patients whose preoperative weight levels are below their ideal weight, and these trends are related to the procedure employed. Control of the acid factor by means other than radical resection should be considered. Data on the preoperative nutritional status as well as on the postoperative weight trends of the patients reported on would seem highly desirable in the evaluation of the effectiveness of any operation for duodenal ulcer.

ETIOLOGY OF ANTISOCIAL BEHAVIOR IN DELINQUENTS AND PSYCHOPATHS

Adelaide M. Johnson, M.D., Rochester, Minn.
and
S. A. Szurek, M.D., San Francisco

Our thesis is that parents' unwitting sanction or indirect encouragement is a major cause of, and the specific stimulus for, such antisocial behavior as fire-setting, stealing, truancy, and unacceptable sexuality displayed by young delinquents or their adult counterparts, the psychopaths. The delinquencies under consideration are those arising in apparently "normal" families of good reputation and are not those largely determined sociologically in slum areas or juvenile gangs of any economic level.

The conclusion proposed here has emerged from studies carried out by us during the past decade, and it requires considerable amplification and evidential documentation. Some of the material has been published previously by us.¹ By means of study and concomitant treatment of the parents as well as of the child involved in the antisocial behavior, it becomes unmistakably evident that one or occasionally both parents derive unconscious, and less frequently conscious, vicarious gratification of their own poorly integrated forbidden impulses in unwittingly sanctioning and fostering such behavior in

the child. In every patient brought for treatment, in whom simultaneous intensive study of the parents was possible, the child's defect in conscience was traceable to a like defect in the parents' own poor resolution of unconscious impulses to similar antisocial behavior. Thus, just as normal parents derive vicarious gratification from good behavior in their children, parents who have poorly integrated forbidden impulses apparently derive gratification from the bad behavior of their children.

In so complex a setting as family life, a multiplicity of variables operates, so that no single secondary cause for delinquent behavior can be isolated. As already mentioned, it is our contention that unwitting permissive sanctioning by parents is a major and specific cause for children to live out antisocial impulses. Scientific proof of causation is not satisfied by demonstration of the invariable presence of the suspected cause (parental sanction) whenever the effect (antisocial behavior of children) is observed. It must be demonstrated also that the suspected cause does not occur unless the effect is also seen. This has been our experience. We have never observed these parental permissions without antisocial behavior in at least one child who had been chosen as a scapegoat. Our thesis is not merely reasoning based on *post hoc, ergo propter hoc*; the enmeshing interplay of parent and child in the affected area bespeaks more than a fortuitous time sequence.

ENLISTMENT OF A SCAPEGOAT

Often a parent may unconsciously select only one child to be the scapegoat in a family of several children, the others being exempted and consequently well behaved. An adopted child may be particularly suitable for such a role, since the encouraged misbehavior may be attributed to heredity rather than to parental encouragement. The young boy who was born when a girl was badly wanted, or the younger of two sons who superficially

resembles the younger of two uncles who was "spoiled and no good from the start," is a likely candidate. Formulas for the unconscious selection of the unfortunate scapegoat are multiple. So also are the devious patterns for impressing him into his tragic role.

An example of this mechanism is shown in the following instance. A mother was alarmed to find her 5-year-old younger son playing with matches. The son reminded her of her "no-good" brother Ed, who also had set fires and who had aroused her jealousy because he was her father's favorite. She warned her son to stop playing with matches: "I told him fires should be only in a stove, a fireplace, or for cigarettes." All was well, so far. "But," she added, "I said that if he insisted on fires, we would burn some papers in the sink. My husband said it was stupid to burn papers in the sink, but I thought that it was better than burning the house down the way my brother Ed nearly did twice."

Note the vacillation between the mother's conscience-dictated prohibition and the permissive loophole of "... if he insisted. . . ." This telescoped case report provides clues leading to eventual explanation of (1) the selection of the scapegoat, (2) the choice of antisocial behavior to be fostered, and (3) a technique, concocted of vacillating prohibition and permission, for inadvertently encouraging the behavior. The subtle permissions and encouragement defy detection unless parent and child are studied intensively by one experienced in ferreting out significant clues.

EMERGENCE OF CONSCIENCE

A child's conscience is made, not born. It is not inherited ready-made but is developed, especially during the first six years of life, primarily through identification in great detail with the total behavior of parents. This identification or mimicry embraces the conscious and unconscious operations of the parents. To an equal extent, conscience develops from the parents' conscious and unconscious image of the child and from their concepts and hopes for a child. The normal mother never doubts that in a few years her children will learn absolute honesty about money. To her, there is no choice; it is axiomatic that stealing is absolutely forbidden. When a parent says, "Jimmie has never stolen yet, but somehow I worry that he may some day," further study always unearths the mother's own poorly integrated impulses to cheat and steal. The hostile content of her doubts about Jimmie is soon revealed, and there are scarcely formed fantasies of using him as her scapegoat to steal for her.

Paralyzed consternation may overtake a parent whose 7-year-old has just taken a dollar from the dresser or displayed a trinket pilfered from the dime store. Why this anxiety, confusion, or even undue hostility? Why not manage the matter firmly and directly? There is a reason. An impulse in the parent, alternative to complete honesty, compels vacillation and hedging rather than the establishment of a clear limit. That impulse may explode into a rage, with threats of the reformatory. Such a parental reaction suggests to the child that his impulses to steal really may get out of hand. In his unsophistication and dependency, he is inclined to accept the painting of Dorian Gray as a true image of himself.

The mature, normal parent neither anticipates impending disaster nor dismisses monetary transgression as

trivial. Instead, the problem is resolved promptly without anxiety or guilt. The mother says, "Susie, you took the dollar from the dresser; please get it for me at once. No one may take another's money without asking permission." She insists that the money be returned promptly. Of the dime-store trinket she tells Johnnie firmly and without anxiety that it is wrong to take things without paying for them. She accompanies Johnnie to the dime store to return or pay for the article. Storekeepers are accustomed to parents coming on such errands, and usually accept the proper restitution. Such a parent is neither the nagging, checking detective nor the permissive, lax condoner. She does not dismiss recurrent minor thefts with the rationalization "Oh, he will outgrow it," only to bring the child for treatment when the school complains of thefts.

Many parents, whose own poorly integrated prohibitions permit them to overlook recurrent slight offenses, suddenly react with guilt and alarm at the first suggestion of criticism from outside the home. They respond with righteous accusations and punishment. The child is confused and angry at what now appears to be parental betrayal. If the child is not too ashamed or frightened, he may give voice to his recollections of similar parental deceptions, initiating a vicious cycle of hostile blackmail and mutual corruption.

We cannot cheat a child or anyone else and expect the child to overlook it. There are many variations on the main theme that deception encourages deception, such as the admonition of the mother who says to the child, "Here is a dollar, but don't tell your father." A parent may not smile at keeping too much change from the grocer and expect his child to be honest about money. A mother may not encourage children to understate their age to enter a movie at half price and expect them to be honest. Similarly, to count integrity as a virtue is difficult for a child who repeatedly has experienced parental promises made lightly and broken without explanation or apology. A sincere apology or explanation is always accepted.

The psychopathic personality or "psychopath" of later years is the grown-up delinquent child with defects in conscience, who is in court for theft, burglary, forgery, or worse. In every such instance providing us opportunity for careful study, a long history is revealed of parental sanction of antisocial offenses, "bailing out," and "fixing"; the pattern may include illicit excuses to the teacher for daughter's absence from school, repeated restitution for son's bad checks, and dishonest support of the young transgressor against a neighbor's property.

TRUANCY

We have found that parental coldness and rejection are insufficient causes of truancy from home. These attitudes are nonspecific stimuli to which many children who do not run away are also exposed. Truancy usually results from suggestion at home, sometimes relatively overt, sometimes disguised and difficult to detect.

The 6-year-old child, sensing coldness and rejection, may say angrily, "You don't love me. Nobody loves me. I hate you all!" Then, and not infrequently, the specific stimulus may be applied by the parent in words such as, "Very well! Why don't you just pack your bag and go live some place else if you think we're so awful?" We have

observed that some parents even go so far as to pack the child's suitcase, which is a terrifying experience for the child. The suggestion to run away comes more frequently from inside the home than outside, for rarely do small children tell their friends that their parents are "mean" or get suggestions from other children to leave home. More subtle, less direct, but equally effective sanctions for truancy are the rule.

An example of parental approval and encouragement of this type of behavior is found in the case of 6-year-old Stevie, who had been running away since he was 4. His father recalled the boy's episodes of exploration in inordinate detail. This fact struck us as most significant. The father reported that during the same two years he himself had been forced to discontinue his work as a transcontinental truck driver, a job in which he reveled, for work that confined him to the city. It was striking to observe this father urging Stevie to tell of his most recent escapade and prompting with an eager reminder when the child guiltily hesitated. The account obviously fascinated the father. Suddenly the father angrily stopped the child with, "That's enough, Stevie; now do you see what I mean, doctor?" Stevie could not fail to sense his father's keen interest and pleasure in his tale on each return home, despite the inevitable whipping. The father was a kind, well-intentioned man who rightly feared for his little son's safety. He was, however, entirely unconscious of the fact that the stimulus of his own thwarted need to travel and his interest in Stevie's adventures was easily conveyed to this small, bright boy, of whom the father said, "Stevie's really a good kid. He would follow me around the top of a wall 50 feet high."

A smile of tacit but unwitting approval often belies a parent's complaints of impulsive and daring behavior of the child brought for treatment. Children are masters at sensing parental interest or gratification, however subtle, at a tale of naughtiness. Even if punishment comes after the interest-arousing narrative, the damage has been done. If even disguised parental pleasure preceded the spanking, the child will repeat the performance. To please mother or father is worth the punishment, although the contradiction between seduction, through evincing pleasure, and the spanking is impossible for the child to reconcile.

SEXUAL MISBEHAVIOR

The same pattern of selection of a scapegoat, choice of misbehavior to be suggested, and subtle guidance of the child into antisocial activity is seen in sexual misbehavior as in fire-setting, stealing, truancy, and other forms of delinquent behavior. Again, the variants of the theme are multiple. Parental suspiciousness or acute anxiety suggests that alternate forms of behavior may well occur on adolescent dates and might even be accepted; inordinate maternal curiosity regarding daughter's experiences with boys carries implied sanction; freely voiced interparental accusations of sexual aberrations stunt the child's growth of conscience in these areas; misguided, too exciting discussions about sex constitute unwitting approval; encouragement or display of undue degrees of nudity at home provides excessive permission. Illustrations are endless, but the following case is a good example.

The mother of a girl of 9 was excessively concerned lest her daughter misbehave when she began dating. Examination and analysis of these premeditated fears revealed a submerged impulse in the mother to have the child so act substitutively because the mother herself was sorely tempted to promiscuity. When the child became older, detailed suspicious questionings and dire warnings constituted unwitting permission, because the mother transmitted to the daughter a maternal concept of the girl behaving otherwise than acceptably.

Lack of faith from a source that should impart strength weakens the inhibitions. Again, the mere hint of a little too much interest and a slight shadow of pleasure at hearing tales of daughter's nocturnal adventures loom larger in the daughter's mind than scolding or punishment.

These relationships are universally present and may be discovered if there is the will to do so, together with the skill and patience to detect them. This usually requires close collaboration between two therapists, one for the parent and one for the child.

It is amazing to discover the extent to which intelligent families of respectable status accept or even encourage varying degrees of nudity, including the complete variety, with conversion of the bathroom and its gamut of functions into something resembling a family Grand Central Station. This attitude is accompanied by a "frankness" regarding procreation and its antecedent ramifications carried far beyond the needs of the curious child. The setting is not the bridge table or locker room but the home, with children and adolescents who are inclined to be a bit abashed by both the content and the artificiality of the proceedings.

Much of this spuriousness is perpetrated in the name of Freud, who was actually an extremely conventional person. True, he recognized the biological curiosities of children, their confusion regarding the two sexes, and their frustrations in competing with one parent for the affections of the parent of the opposite sex. But always in such matters Freud was the advocate of moderation and restraint; the parent was to answer the child's specific questions about sex but not to deliver a lurid oration that was gratuitously extended far beyond the answer sought. He decried equally either a reaction of guilt and horror to a child's questioning or an anxious outpouring of unsought information that is more confusing, even if accurate, than reassuring. He never encouraged exhibitionistic displays of nudity around the home, knowing that too much of this only increased children's anxiety.

MALIGNANT SEQUELAE OF FRUSTRATIONS

The degree to which "freedom" is practiced in the best of families is remarkable. Mothers who, under the guise of motherliness, take to bed with them male children who are well beyond infancy or even into adolescence, or fathers whose caresses of adolescent daughters slightly exceed paternal affection, store up grapes of wrath in the child. On the one hand is permissiveness from the ultimate source of permission, the parent, and on the other hand is frustration, born of parental guilt, for not stopping before the beginning.

The sequelae flowing from such combined permission and frustration are as predictable as those from the administration of thyroid hormone to a normal person.

Adolescents in such a dilemma may (1) regress to a more childish perverse sexual outlet, such as exhibitionism, homosexuality, or fetishism, (2) develop a malignant neurosis, (3) disintegrate into a psychosis of suicidal or homicidal content, (4) give vent to volcanic rage, sexually colored, in sexual violence against women, or (5) enact murderous violence against the parent, usually son against mother. Again, there is no dearth of illustrations.

In one case, a mother came to us complaining that her 16-year-old son had recurrent "wild fears he might kill her" and that recently he had become exceedingly obese. Glibly at first, then with anxiety and guilt, the mother characterized the son as "his mother's boy," who liked to lie abed with her. Oblique inferences to his lack of friends elicited the response, "Mom is my girl." His ultimate effort was a regression toward an earlier developmental level, eating enormously, but without success in blanketing the rage engendered from permission and prohibition. The frightening urge to kill brought mother and son to treatment.

Too often the case ends in a state hospital or a newspaper headline. Nothing is mysterious about the cause of sexual crimes when we have a chance to study the parents of the offender.

MANAGEMENT OF DELINQUENCY

The evidence for the propositions expounded here, or, more properly, illustration of the facts recounted, lies at hand in every case of antisocial behavior in the group of persons under consideration. But this evidence must be sought with diligence, gentle persistence, and skill, usually by two therapists collaborating closely. Only the experienced observer will detect the clues and pursue them with such oblique and subtle questioning as will yield the truth. Direct questioning is fruitless. Unearthing of parental sanction for antisocial behavior in children is one of the most formidable challenges that confront psychiatrists.

Treatment of the parent is fraught with difficulty. If the parent has provided conscious sanction of the child's delinquency, treatment is usually impossible. If the parental role was unconscious, the uncovering of the parent's problems is a miserable or hazardous ordeal, and at times the therapy requires hospitalization.

Since parental sanction of antisocial behavior is usually unconscious, it is legitimate to question whether widespread lay knowledge of the role of parents in delinquency promises to limit the phenomenon. The thesis would appear to be defensible that the mischief perpetrated by the poorly integrated parents under consideration might well be curbed if it were generally conceded that delinquent behavior may not, without searching scrutiny, be ascribed to heredity, "bad companions," poor schools, or divorce. The poorly inhibited antisocial impulses of adults may not then so readily find expression in the encouragement of scapegoats. It is true that such adults would then become neurotic, evidencing emotional conflicts in which conscience has prohibited direct expression of an urge to antisocial action. Troublesome as such neuroses may be, in the form of phobias, compulsions, conversions, or a hundred other neurotic expressions, they are preferable to antisocial behavior, with its threat of perpetuation through generations. In most in-

stances, a neurosis, with conscience holding the fort, is more amenable to therapy than delinquency, in which the conscience is too weak or in abeyance. The therapist apportions no blame but prefers to interpose a barrier of understanding that would divert conflicts of parents toward individual neuroses rather than toward vicarious gratifications through the misbehavior of children.

SUMMARY

We have assimilated material from more than a decade of research and collaboration dealing with the cause of antisocial behavior in "good" families. The same cause is involved in the delinquent and in the psychopath, who is just a delinquent grown older. Of course, the more private family delinquencies in some instances may overlap the sociologic or gang antisocial behavior. By means of simultaneous psychotherapy of the parents and the child, we observed that the parents unwittingly condone and foster the child's living out the parents' own poorly inhibited antisocial impulses, so that the parents may achieve vicarious gratification. This obtains for stealing, recurrent fire-setting, sexual destructiveness, vandalism, and serious recurrent criminal behavior. A defect in conscience is permitted to develop in the child by the parents so that the parents unconsciously can achieve pleasure by permitting the child to misbehave seriously. The frequent parental hostile destructiveness toward the child who is the scapegoat and the unique significance of the choice of this particular child as scapegoat always can be discovered by thorough study of the parents.

A multiplicity of variables of mixed quality and quantity enters into the family rearing of any child, but the specific stimulus for the actual living out of a child's antisocial behavior is the unconscious, less often conscious, sanction from the parent. This specific behavior of the child is traceable to a specific defect in the parents' own conscience or integration in this area of behavior. It is advocated that there be a disseminated knowledge of these origins of delinquency, aimed at the erection of parental conscience barriers against the fostering of vicarious misbehavior, since such behavior may be transmitted from generation to generation through interpersonal living. Individual neuroses that may result, regardless of their severity, are more amenable to treatment than is the delinquency complex.

626 5th St. S. W. (Dr. Johnson).

Cross Resistance to Antibiotics.—The selection of alternative choices of therapy should be guided by the information contributed by cross resistance studies. Aureomycin would probably not be selected as alternative to terramycin, or vice versa, in refractory conditions due to resistance. In some bacterial genera and species, organisms resistant to aureomycin and/or terramycin are also resistant to chloramphenicol. Organisms resistant to viomycin and neomycin may be resistant simultaneously to streptomycin. Carbomycin would probably prove ineffective against erythromycin-resistant organisms, or vice versa. Among organisms which were resistant to aureomycin and terramycin, exposure to erythromycin produced a resistance to penicillin in experimental studies. With the problems of resistance and cross resistance so apparent, the *in vitro* antibiotic sensitivity test should be done on certain micro-organisms.—M. H. Fusillo, B.S., and Col. D. M. Kuhns, (MC), Cross Resistance of Bacteria to Antibiotics, *U. S. Armed Forces Medical Journal*, November, 1953.

IMMUNOHEMATOLOGICAL STUDIES IN HEMOLYTIC ANEMIA

Israel Davidsohn, M.D.

and

Wilma Spurrier, M.T., Chicago

The purpose of this paper is to report three groups of observations, dealing with the serologic diagnosis, the pathogenesis, and the serologic changes resulting from hormonal therapy of so-called autoimmune hemolytic anemia. The unique feature of this type of acquired hemolytic anemia is that patients afflicted with it produce antibodies or antibody-like substances capable of reacting with their own red blood cells. This is not in accord with the old dictum that an individual does not produce antibodies against antigens of his own tissues. Exceptions from this rule in the form of hemolysins reacting with the host's own erythrocytes in patients with hemolytic anemia have been reported early in the century.¹ These early observations could not be reproduced, except in isolated instances, for over 30 years, until it was found that the antibodies in question are "incomplete," by which is meant that they require special conditions to become manifest, such as the presence of protein rich or other macromolecular diluents (for example, bovine albumin or human serum) or highly sensitive enzyme-treated red blood cells or use of a technique known as the antiglobulin or Coombs test. Since these techniques have been applied, autoantibodies have been found in large numbers of acquired idiopathic and symptomatic hemolytic anemias. The practical application of these recent developments is that the presence of autoantibodies expressed as a positive direct antiglobulin test or Coombs test is recognized as a significant finding in support of the diagnosis of acquired hemolytic anemia.

SEROLOGIC DIAGNOSIS

Autoantibodies in acquired hemolytic anemia are found in two forms. They are attached to erythrocytes and are known as cell-bound autoantibodies. Chemically, they are globulins as are all antibodies. They can be detected by adding, to red blood cell suspensions, antihuman globulin immune serum produced in rabbits injected with human globulin. This is the so-called direct Coombs test or antiglobulin test. Evans and Duane² described a technique permitting approximate quantitative estimation

of the titer of the direct Coombs test. Autoantibodies are found also as free antibodies in the plasma and serum of patients with this type of anemia. They are detected by mixing the patient's serum with his own red blood cells, with cells of the same blood group as his, or with cells of group O. In the technique employed here, the red blood cells were suspended in a 30% solution of bovine albumin, and the patient's serum was diluted progressively with serum of group AB, which lacks isoagglutinins. Saline as diluent for the serum and as suspending medium for the red blood cells is not suitable for demonstration of incomplete antibodies, but it is used as a preliminary step to the so-called indirect Coombs test for detection of free autoantibodies. In this latter test, saline suspensions of red blood cells are added to saline dilutions of serum. After incubation, which does not lead to a visible reaction, antiglobulin serum is introduced to bring out the coating of the red blood cells with antibodies.

In the third technique, enzyme-treated red blood cells are used. This makes the cells extremely sensitive to antibody action. (For details of tests and other technical procedures referred to in this paper, see footnote 4.) In most instances, cell-bound and free autoantibodies are found simultaneously. When only one is present, it is most frequently the cell-bound variety, which gives the positive direct Coombs test. Less frequently the opposite is true; only free autoantibodies are found. The latter may have special significance and will be discussed later. There is no reason to assume that cell-bound or fixed antibodies and free or circulating antibodies are different from each other. Actually, there is evidence in support of the conception that, as a rule, autoantibodies attach themselves, at first avidly to erythrocytes and appear as free antibodies in the plasma only after the red blood cells have become saturated with them. In other words, according to this conception, free antibodies constitute an overflow.

The following observations can be cited in support of this idea: Red blood cells giving a positive Coombs test cannot be made to absorb significant amounts of free autoantibodies from the serum; autoantibodies can be eluted from Coombs-positive red blood cells with proper techniques; absence or low titers of free autoantibodies are found most frequently together with low titers of the direct Coombs test; and finally, cells with high-titered direct Coombs tests are more frequently found in bloods with free autoantibodies and rarely in bloods without such antibodies.

Occasionally, free autoantibodies may be present in bloods with negative direct Coombs tests. In our series of 38 patients in whom autoantibodies were studied, 5 (or 13%) had a negative direct Coombs test, whereas one-third of patients with the positive direct Coombs test had no detectable autoantibodies (table 1). Examples of

cases of the former variety and the explanations of at least some of them will be discussed later. Judging from reports in the literature, tests for autoantibodies in hemolytic anemia are frequently limited to the direct Coombs tests. Tests for free autoantibodies are reported less frequently. The lack of interest in free antibodies is in accord with the prevalent opinion that tests for free antibodies have nothing to offer in line of diagnosis not already provided by the Coombs test. In the light of the preceding discussion, tests for free autoantibodies may be of value in

TABLE 1.—*Relation Between Cell-Bound and Free Autoantibodies in Hemolytic Anemia*

Type of Anemia	No. of Positive Coombs Tests	Autoagglutinins			
		Positive		Negative	
		No.	%	No.	%
Acquired idiopathic.....	35	24	69	11	31
Acquired symptomatic.....	21	14	67	7	33

Type of Anemia	No. of Cases of Positive Auto-anti-bodies	Coombs Test			
		Positive		Negative	
		No.	%	No.	%
Acquired idiopathic.....	24	22	92	2	8
Acquired symptomatic.....	14	11	79	3	21

three ways. In the first place, 13% of cases of autoimmune hemolytic anemia in our series of 38 would not have been diagnosed serologically with the direct Coombs test alone (table 1). To attribute it entirely to technical pitfalls of the Coombs test is not in accord with our experience. To guard against technical sources of error inherent in the Coombs test, all possible precautions and suitable controls were included. The patients in whom free antibodies were discovered although the results of the direct Coombs test were negative fall into two groups: (1) those who had received corticotropin or cortisone therapy before they were first tested and (2) those whose tests revealed low titers of autoagglutinins, frequently detectable with only one of the three techniques used. The explanation, in our opinion, rests on the use of highly sensitive methods of antibody detection.

The second argument favoring inclusion of tests for free autoantibodies in the study of patients with hemolytic anemia is that they may be of value as an indication of the potency of antibody production. In other words, their presence and titer may add to the information furnished by the Coombs test. Thirdly, there are also technical reasons in favor of testing for free antibodies. The Coombs test has its limitations inherent in its complexity and especially in the difficulty of standardization of the reagent, the antiglobulin serum. That difficulty does not apply to most of the techniques used for testing for free antibodies. Furthermore, serum can be stored in the refrigerator for future comparative tests used in following up antibody levels. Red blood cells of the patient, the substrate for the direct Coombs test, do not lend themselves for such control studies beyond a very limited period, at most a week to 10 days. According to an interesting observation first reported by Dameshek³ and more recently confirmed and expanded by one of us (I. D.) with Oyamada,⁴ in some patients free autoantibodies react only with the patient's own red blood cells, while in

others, who constitute the majority of cases, the antibodies react not only with the patient's own erythrocytes but also with red blood cells of other persons, including those of the normally inagglutinable blood group O. This observation may or may not have direct practical significance currently, but it bears watching and deserves further study by gathering more data.

OBSERVATIONS RELATING TO THE PATHOGENESIS OF HEMOLYTIC ANEMIA

The question of the relation between autoantibodies and the hemolytic process has been the subject of much discussion: Is there a cause and effect relationship between the two or are they merely associated phenomena? A case like the one recorded in table 2 illustrates pointedly the justification for the preceding question. A direct Coombs test made on a 37-year-old woman (blood type A Rh₁ Rh₂ [CDE], serologic pattern + -, later + +) with acquired idiopathic hemolytic anemia resulted in a strongly positive response, and free autoantibodies were present. Prior to splenectomy, the patient received 25 pt. of blood, and corticotropin and cortisone were administered. After surgery, the anemic condition improved without further therapy and has remained improved for at least a year. In spite of the patient's clinical improvement and the apparent cessation of the hemolytic process, the

* The red blood cells of the patient were clumped in normal AB serum, in 30% bovine albumin solution, and, in the test in which red blood cells were treated with papain, in the controls without the patient's serum. This explains why no end point could be reached in the titration with the patient's serum.

titer of the direct Coombs test remained high, and the amount of free antibodies remained unchanged. It is not surprising that cases like the one described invite the conclusion that autoantibodies are not the cause of the hemolytic process. Actually, one could arrive at a different conclusion, namely, that the antibodies are only one link in the chain that is responsible for hemolysis. It may be

3. Dameshek, W.: Acquired Hemolytic Anemia: Physiopathology with Particular Reference to Autoimmunization and Therapy, in Proceedings of the Third International Congress of the International Society of Hematology, Cambridge, England, 1950, New York, Grune & Stratton, Inc., 1951, pp. 120-133.

that autoantibodies are preparing the cells for the destruction by the spleen and by other tissues with similar function. Removal of the spleen eliminates the site where the major job of destruction of damaged red cells takes place. This inference would be supported by evidence showing that red blood cells that give a positive Coombs test are functionally inferior to Coombs test-negative red blood cells.

Evans and Duane² studied susceptibility to hemolysis in hypotonic solutions of red blood cells of patients with

* The red blood cells of the patient were clumped in normal AB serum and in 30% bovine albumin solution in the controls without the patient's serum; therefore, no end point could be reached in the titration with the patient's serum.

autoimmune hemolytic anemia. No consistent relationship between increased fragility of the cells and severity of the hemolytic process was demonstrated. Gardner⁵ reported significantly increased osmotic fragility in three patients with idiopathic acquired hemolytic anemia. These and other investigations present a strong argument in favor of an etiological relationship between autoantibodies and hemolysis.

We undertook to investigate further the resistance of red blood cells of patients with autoimmune hemolytic anemia to various damaging influences. Thus far, only preliminary pilot experiments have been completed. They are admittedly crude in execution but are interesting in that they point in the same general direction. More refined techniques are being applied and will be reported later. The preliminary studies included the use of hypotonic solutions of sodium chloride and the effect of low and high temperatures. Distilled water was added to whole blood with a positive Coombs test and to 50% suspensions of Coombs-positive red blood cells in AB serum and in saline. Two patients with idiopathic hemolytic anemia and with Coombs titers of 1:32 and 1:64 showed lessened resistance to hypotonic sodium chloride solutions. Two patients with symptomatic hemolytic anemia who showed no changes in resistance to hypotonic saline had Coombs titers of 1:8. Artificially sensitized type O, Rh-positive cells, with Coombs titers of 1:32, showed no significant lessening of resistance in hypotonic solutions of saline. The results were identical in all suspension mediums.

In another experiment, 50% suspension of red blood cells in the plasma of the same person, in AB serum, and in saline were incubated at from 2 to 5 C. Red blood cells of four out of five patients with acquired hemolytic anemia and with a positive Coombs test showed moderate to marked hemolysis after prolonged icebox incubation. Cold agglutinins were not responsible for the increased sensitivity to low temperature. Normal controls and Coombs test-positive red blood cells of a newborn infant with fetal erythroblastosis and cells artificially sensitized with anti-Rh₀ serum showed no hemolysis under the same experimental conditions. There was no difference depending on the suspension medium used. In other experiments, red blood cell suspensions were subjected to temperatures of 56 C and 60 C. The differences in the hemolysis observed in blood of patients with autoimmune hemolytic anemia and of controls were not sufficiently consistent in the preliminary tests. The preceding experiments show that, at least in some cases, a positive Coombs test and a lessened resistance to certain damaging influences go hand in hand. It is reasonable to conclude that autoantibodies are at least partly responsible for the excessive hemolysis in acquired hemolytic anemia. However, it should be mentioned that spherocytosis, which may be present in acquired hemolytic anemia, may by itself or in conjunction with other factors be responsible for the described manifestations of lessened resistance.

SEROLOGIC CHANGES RESULTING FROM HORMONAL THERAPY

The effect of corticotropin and cortisone on antibodies has been the subject of much recent discussion. Gardner reported a sharp decrease in the Coombs titer in patients with autoimmune hemolytic anemia following cortisone therapy.⁵ The question most frequently posed is: Do these substances inhibit or depress antibody production or do they interfere with the union of the antigen with the antibody? The answer to this question is of more than academic interest. Autoimmune hemolytic anemia offers an excellent opportunity for the study of this problem, because cell-bound and free circulating antibodies are present simultaneously in this condition.

Table 3 gives the results of therapy with corticotropin, 20-40 mg. administered daily to a male patient, 55 years old, of blood type B Rh₁ (CDe). The patient had chronic lymphatic leukemia with autoimmune acquired hemolytic anemia. After 66 days, the direct Coombs test results dropped from titers of 1:64 to 1:1 and later became negative, whereas the titers of free antibodies went down gradually but did not disappear entirely. A second patient (table 4), a 22-year-old woman of blood type A Rh₁ (CDe), with acquired hemolytic anemia possibly due to the toxic effect of chloramphenicol, received a month of intensive therapy with cortisone (1,500 mg.). The red blood cells numbered 2,500,000; the hemoglobin level was 8.8 gm. per 100 cc. (oxyhemoglobin photoelectric colorimetric method); and the serologic pattern was + — — prior to testing. After the therapy, the Coombs test result was barely detectable and similarly low were the titers of free autoantibodies. Two weeks later the Coombs

5. Gardner, F. H.; McElfresh, A. E.; Harris, J. W., and Diamond, L. K.: Effect of Adrenocorticotrophic Hormone (ACTH) in Idiopathic Acquired Hemolytic Anemia as Related to Hemolytic Mechanisms, *J. Lab. & Clin. Med.* 37: 444-457, 1951.

test was negative, but the free autoantibodies were still detectable; after two more weeks the Coombs test was still negative, and the free autoantibodies had disappeared. In this case again, the direct Coombs test became negative before the disappearance of the free autoantibodies.

In several other patients, administration of corticotropin or cortisone had a similar effect on the Coombs test. This result suggests that, at least in hemolytic anemia, these hormonal substances influence the union of the antigen with the antibody before the antibody production is affected. Doing only a Coombs test on the cells of patients with hemolytic anemia who received steroid therapy may lead to the false conclusion that no autoantibodies are present, when, actually, free autoantibodies are still there. It is possible that some statements in the literature to the effect that autoantibodies have disappeared after hormonal therapy are explained in the light of observations just reported.

TABLE 4.—Effect of Cortisone on Coombs Test (Cell-Bound Autoantibodies) and Free Autoantibodies

Date	Direct Coombs Test, Titer	Red Blood Cells	Titer of Autoagglutinins* at 37 C Indirect Coombs Test with Papain-Treated RBC
2/27/53	1:1 †	Own Type A Type O	1:8 Neg.
8/11/53	Neg.	Own Type A Type O	1:32 Neg.
8/28/53	Neg.	Own Type A Type O	Neg. Neg.

* Test for autoagglutinins with the techniques employing serum-albumin diluent and papain-treated red blood cells were negative throughout the entire period of observation.

† Very weak test obtained with special sensitive technique: 1 drop of 10% suspension of patient's red blood cells treated with papain plus 4 drops of Coombs serum. Negative after usual 30 minute incubation at 37 C but positive after 2 hours.

COMMENT

The foregoing observations suggest that free circulating autoantibodies may be the overflow remaining after the red blood cells have first absorbed whatever amount they can hold in the particular case. One of us (I. D.) has reported previously⁴ varying reactivity of free autoantibodies depending upon the source of cells used in the test (patient's own, cells of the same group as the patient, or cells of group O). In some instances only the person's own red blood cells were clumped and not other cells. In other cases the reaction with the patient's own cells was present in higher dilutions than with the other cells. In others again, all red blood cells were clumped to the same degree. The reason for these differences is not known, except that specificity of the antibody and the sensitivity of the particular cells may be involved. The increased agglutinability of the patient's own red blood cells may be explained by the additive effect of the free antibodies and the antibodies already attached to the red blood cells. The red blood cells giving a positive Coombs test have shown, at least in some cases, evidence of lesser resistance to high and low temperatures and in hypotonic solutions of sodium chloride. This may create a handicap just sufficient to facilitate excessive hemolysis when such red blood cells

are exposed to the damaging influences of a hyperactive spleen. Cortisone and corticotropin had a more pronounced inhibitory influence on the union of the antigen with the antibody than on antibody production in several cases of autoimmune hemolytic anemia.

SUMMARY AND CONCLUSIONS

The direct Coombs test and the test for free autoantibodies are both recommended for the study of autoantibodies in hemolytic anemia. Dependence on the Coombs test alone may lead to false negative results, because, under various conditions, notably after corticotropin and cortisone therapy, the Coombs test may become negative, whereas the free autoantibodies may remain in the circulating blood at the same or at the reduced levels. Technical reasons also recommend testing for free autoantibodies but only as an additional test and never to the exclusion of the Coombs test. In some instances Coombs test-positive red blood cells showed lessened resistance to certain damaging influences. This favors the view that there is a cause and effect relation between autoantibodies and the hemolytic process. Corticotropin and cortisone therapy seemed to inhibit the binding of the antibody by the antigen. The influence upon the free antibodies was less pronounced.

An Even Keel in Orthopedics.—More than half the boys leaving public schools have lost their tonsils, and as many as four in five their foreskins. One wonders how many have been subjected to wedged shoes and so-called remedial exercises: certainly a very large number. . . . A child who intoes because of tibial torsion counteracts this by flattening his feet. If valgus wedges are prescribed he will intoe even more and will probably be taken elsewhere. None can cavil at correction of valgus feet in a child with knock-knees, but any wedge is too great that throws the foot into varus; nothing encourages knock-knee so much as pes varus. Normal children go through a phase of knock-knee, which soon disappears if they are lucky enough to avoid treatment; if, on the other hand, they have to contend with a man-made pes varus, they usually still get well, but much more slowly. . . . When I was a child our nannies made us turn our toes out; nowadays our physiotherapists would make us walk on the outer sides of our feet: better nanny's valgus than physio's varus. Another very bad custom among many physiotherapists is the passive stretching of tight posterior calf muscles, which must respond by becoming tighter still; physiological relaxation is promoted by active dorsiflexion without pronation. . . . Misuse of rest now provides a less abundant harvest for the bonesetter than it did. But it is still one cause of porotic bones, damaged growth plates, and stiff joints. Splinting paralysed parts did not stiffen joints when these were put daily through their full range of movement subject to the dictates of pain. It was the misuse of splints, and an exaggerated campaign against passive movements in all circumstances, that produced the stiffened joints in paralysed limbs. Against these bad results of bad treatment there arose a worse reaction. Painful limbs in the active stage of poliomyelitis were moved, not with restraint, but forcibly and mercilessly with a violence that tortured patients, promoted spasm in still active muscle and even caused myositis ossificans. . . . The strengthening effect of muscle reeducation has obscured its other principal effect—the physiological promotion of relaxation in unparalysed opponents. This can be encouraged before any power has returned to the paralysed muscles if the patient makes early attempts to contract them. Active exercise, the basis of physiotherapy, must be tempered with wisdom.—H. J. Burrows, M.D., *Proceedings of the Royal Society of Medicine*, October, 1953.

RADIOLOGICAL ESTIMATION OF PELVIC EXPANSION

Arthur Weinberg, M.D., Far Rockaway, N. Y.

It has long been recognized that the usual obstetric patient will deliver her second and third babies with greater ease and with shorter labor than her first. This is true even though customarily the birth weight of each succeeding child shows a slight increase over that of its predecessor. The decrease in dystocia in each succeeding delivery has in the past been attributed to the dilatation and lacerations of the soft parts of the birth canal, the lower uterine segment, cervix, vagina, and perineum. On this basis one would expect all multiparous deliveries, without positional dystocia, to be easier, provided the contractions are efficient and the increase in the size of the baby not excessive. However, an appreciable percentage of primiparous and multiparous second stage labors resemble each other closely. It is, therefore, necessary to consider that other factors may be responsible for inconsistent prognostications of multiparous deliveries.

Heretofore the incidence, degree, and clinical significance of pelvic expansion during pregnancy and labor have never been accurately estimated. Allen¹ has noted that the usefulness of pelvimetry at the midplane level is limited, owing to the physiological increases in the diameters possible during labor. Moir and others² have stated that, if pelvic measurements are inadequate in the cavity or outlet only, some 25% of easy deliveries may occur, especially in multiparas, because of pelvic expansion. Allen has further remarked that at the midplane the difficulties of deciding whether vaginal delivery is possible are even greater than at the inlet. "This is partly because of greater moulding of the skull and partly because the diameters at these lower levels are capable of physiological increase during labor." Stander (1945), for example, considers that an exaggerated Sims position will increase the posterior sagittal diameter of Klein at the outlet by an average of 7.5 mm. and occasionally by as much as 40 mm. Morris (1947) drew attention to the possibility of dislocations and fractures occurring in the region of the sacrococcygeal joint. Marked widening of the symphysis has been reported.

In previous investigations on the subject,³ the symphyseal spread and the sacroiliac joints were measured in nulliparas, primiparas, and multiparas. Regarding the

pubic articulation, the symphysis regularly undergoes relaxation with an average increase in width of 3 to 4 mm., there being no essential difference in primiparas and multiparas. The most striking finding has been the tremendous variation in symphyseal spread of different persons. The maximum was 30 mm. and the minimum 3 mm. Relaxation begins in the first half of pregnancy, progresses until the last two months, and is affected in varying degrees by parturition. Retrogression begins immediately after delivery and is usually complete in four months. Abnormal separation of the symphysis pubis sufficient to be considered pathological separation has occurred in 25% of the cases.

In no previous study have the effects of symphyseal spread, subluxation of the sacroiliac joints, or other factors been considered as factors in pelvic expansion. Expansion at the midpelvis has been assumed by Moir and others but has never been accurately estimated.

The question of whether the true bony pelvis undergoes significant expansion before or during labor is certainly more important than how much molding a head can safely undergo, since pelvic expansion is always safe, whereas molding may be dangerous. By studying 171 pregnant patients who had x-ray pelvimetry by the same technique 10 days before term of two or more pregnancies, it has been possible to estimate the degree and frequency of pelvic expansion during pregnancy and labor and to estimate its clinical significance.

EFFECT OF SUCCESSIVE PREGNANCIES ON PELVIC INLET

Coronal Diameter (Greatest Transverse of Inlet).—In 150 women of whom films were made at the end of the first two pregnancies, the average increase in the greatest transverse of the inlet was 3.4 mm. This is significant clinically, for even in extreme degrees of molding it is doubtful that more than a 3 mm. reduction in any diameter is achieved. If the average transverse diameter of this inlet is 135 mm., this expansion is about 2.5%. In 43 women who were studied at term of the second and third pregnancy, the average increase was less, 2.5 mm. or almost 2%. The largest increase was 10 mm. Eighteen per cent showed no expansion after the first delivery, and 28% showed none after the second delivery.

In consideration of the accepted limits of accuracy of x-ray pelvimetry, the degree of molding that can be safely allowed, and, because a change of 5 mm. represents 4% of the 15% clearance allowed by Mengert⁴ in his estimations of dystocia, it was decided to consider any change of 5 mm. or more as significant. This amount of expansion occurred in 52 of 150 cases, or 34% of patients studied at term of the first and second pregnancy, and in 9 of 43 cases, or 21% of those studied at term of the second and third pregnancy. Of the 23 patients in whom films of the pelvis were made at term of the first, second, and third pregnancy, 59% showed greater expansion of the transverse inlet diameter between the first and second delivery and 32% greater

expansion between the second and third delivery. In only two of the seven cases in which there was more increase between the second and third delivery was there evident cause for the expansion, such as a much larger baby or a difficult delivery. Four per cent increased the same amount in each gestation, and 4% showed no change after either delivery.

In 50% of these cases there was an increase in the transverse inlet diameter in each pregnancy. In 23% there was an increase after the initial delivery only, and in 14% only after the multiparous delivery.

Sagittal Diameter (True Conjugate).—There was no consistent or significant change in the true conjugate or the anteroposterior diameter of the inlet. Any change in the capacity of the pelvic inlet, therefore, is due to an increase in the coronal diameters. The increase is reflected as an increase in area, only proportional to the linear increase of the transverse diameter involved.

MIDPELVIS

In considering the change between nulliparous and primiparous patients at term, the average increase of the interspinous diameter in 144 cases was 3.7 mm. The average increase in the interspinous diameter that occurred between the second and third delivery was 2.8 mm. The largest change was 16 mm. In 10%, the increase was 10 mm. or more. One patient in each group showed a 1 cm. decrease without evident clinical cause.

It is accepted that 10.5 cm. is the average interspinous diameter. The margin of clearance at this level is much less than at the inlet, and, therefore, a 0.5 or 1 cm. increase is certainly significant. An increase of 1 cm. is about 10% and is two-thirds of Menger's 15% variation allowed for estimation of midpelvic dystocia. An increase of 1 cm. in some cases of contracted midpelvis would raise the midpelvic index above 13.5 and could explain successful delivery with a smaller index.

Of the 23 patients on whom x-ray pelvimetry was performed in three successive pregnancies at term, the interspinous diameter in 52% increased more between the first and second pregnancy than between the second and third. In 26%, the reverse was true. In 4%, the increase was equally distributed, and, in 18%, there was no increase involved in any pregnancy.

In the same series, 35% showed an increase in the interspinous diameter after both pregnancies, 30% showed an increase only after the first pregnancy and 18% only after the second pregnancy. In 17% there was no increase after either delivery.

Sagittal Diameter of the Midpelvis.—There was no definite increase in the anteroposterior diameter or its posterior sagittal component at the midpelvis. Any increase in midpelvic capacity in successive pregnancies would, therefore, be due to the linear expansion of the interspinous diameter.

SEPARATION OF SYMPHYSIS

Pathological or excessive symphyseal spread—five or six times the prepregnant distance—occurred in 4 of the 171 patients studied, an incidence of 2.4%. When it occurs, coronal measurements at all levels of the pelvis are enlarged. At the inlet, the transverse diameter was increased from 6 to 9% and the interspinous diameter

of the midpelvis from 3 to 8%. Since the spread between ample and contracted pelvis is only 15%, these figures for pelvic expansion in conjunction with symphyseal spread are significant. The pelvic expansion in conjunction with symphyseal spread for one patient was:

	Gravida 1	Gravida 2	Gravida 3	% Increase
Transverse of Inlet, Cm.....	15.2	15.6	16.6	9.2
Interspinous, Cm.....	13.0	13.2	14.0	7.8
Symphysis, Cm.....	0.6	1.5	3.0	500.0

COMMENT

I believe that coronal expansion of the pelvic inlet has been demonstrated in the great majority of pregnancies and to a significant degree in about one-third of the cases. These questions remain to be answered. Does the expansion occur during pregnancy, labor, or delivery? The expansion occurs mostly during pregnancy, but also to some extent during labor and delivery. What are the factors that determine whether expansion will occur? This study showed that the degree of expansion is not dependent on the age of the patient, the weight of the baby, or the difficulty of delivery. The only factor that was significant was that the incidence and degree of expansion was more pronounced in primiparas than in multiparas. Is the expansion permanent? The pelvic expansion is permanent, except when it is accompanied by pathological symphyseal spread, in which case coronal contraction occurs simultaneously with the reduction of the separation of the symphysis in the late puerperium (six months).

Can we rely on expansion in a clinical sense? Many yardsticks have been applied to the radiological estimation of pelvic capacity, but they all have the disadvantage that in a small percentage of cases relatively easy deliveries may occur with a pelvis with dimensions that lie in the dystocia range.⁵ This has led some investigators⁶ to discredit the establishment of criteria for dystocia and instead to substitute a trial of labor. Because of the pelvic expansion that occurs in the majority of cases during pregnancy and labor, it would be wise to reevaluate the standards for dystocia. Since the criteria were established not arbitrarily, but by the results of experience, and in view of the fact that not all pelvis expand during pregnancy and parturition, I suggest that, in cases in which the dimensions are within 5 to 10% of the lower limits of eutocia, a trial of labor is justified both in primiparas and multiparas. In the majority of cases, moderate expansion of the pelvis is expected in successive pregnancies and to a limited extent in the current pregnancy and parturition.

SUMMARY AND CONCLUSIONS

Significant pelvic expansion occurs in about one-third of all pregnancies. The expansion is permanent, except when accompanied by pathological symphyseal spread. Since the conditions under which expansion occurs are inconstant, a trial of labor is recommended if the dimensions are within 5 to 10% of the eutocia levels at the inlet and midpelvis in both primiparas and multiparas.

THE CONTRACTED OUTLET

D. Frank Kaltreider, M.D., Baltimore

The recognition of contraction of the pelvic outlet is almost as old as the recognition of the contracted inlet. Williams¹ cites reports by Deventer, de la Motte, and Smellie of isolated cases of outlet contractions. Breisky,² in 1870 recommended the examination of the intertuberos diameter and invented a pelvimeter to measure it. Klien³ measured the posterior sagittal diameter of the outlet and made the statement that if the intertuberos diameter were 8.5 cm., it would be necessary for the posterior sagittal diameter to be 7 cm. Williams⁴ and Thoms⁵ popularized the sum of the intertuberos and the posterior sagittal diameters in this country in the first and second decades of the present century. They recommended 15 cm. as a borderline sum, expecting little difficulty above 15 cm. and increasing difficulty below it.

MATERIALS

These two measurements of the outlet, the intertuberos and the posterior sagittal diameters, are easily obtained. In fact they are the most easily obtained measurements of the pelvic cavity. In order to determine exactly to what use they could be placed in our clinic and in order to determine whether the use of this sum could be of sufficient prognostic value to determine management of the patient before the onset of labor (for example, elective cesarean section in marked contraction), our material was analyzed as far back as 1947. The material consists only of those patients in whom roentgen pelvimetry was done, since the correlation between clinical and x-ray measurements seemed desirable. There were 2,491 patients in whom pelvimetry was done roentgenologically. From this group the following patients were eliminated (a) all patients who had been delivered by cesarean section (330), except for those with outlet contraction after labor (13); (b) all those who had abnormal presentations (125), such as breech and transverse lie; (c) all patients delivered by midforceps (135), midforceps being defined as an application on a fetal head that has not reached the perineum, but when the biparietal di-

ameter has transversed the inlet; and (d) patients with infants weighing under 2,500 gm. and above 4,000 gm. Thus the material consists of all vertex deliveries (1,866) in which labor proceeded to full dilatation of the cervix and terminated spontaneously, by low forceps or by cesarean section in infants weighing between 2,500 and 4,000 gm. There were 35 deliveries for which no record is available.

These patients were then analyzed in the following manner. The various yardsticks for determining outlet contraction were correlated with the percentage of difficult deliveries. Difficult deliveries are defined as those in which (1) excessive traction was necessary to consummate vaginal delivery; (2) if rotation was indicated, difficulty in rotation was encountered; (3) cesarean section was done after full dilatation of the cervix because of lack of progress in the second stage with good contractions, with or without attempts at forceps delivery; and (4) the infants showed evidence of intracranial hemorrhage, whether the infant was discharged from the hospital alive or dead.

RESULTS OF ANALYSIS

By treating the above material in this fashion, the sum of the clinical intertuberos and posterior sagittal diameters was first examined at 0.5 cm. levels. Figure 1 shows the results. It should be noted that, in this particular type of system, when the sums become smaller there should be an increasing amount of difficulty. It can be seen that this is not so in this graph. There could be two reasons for this. 1. We cannot measure the intertuberos and posterior sagittal diameters accurately in our clinic. 2. This type of criteria is not the best for the demonstration of outlet contraction. To test the first hypothesis, patients who had a clinical intertuberos diameter measurement between 8.6 and 9 cm. were examined roentgenologically and the measurements compared. The most frequent readings were between 10.1 and 11.5 cm. with a spread between 8 and 13 cm. When one adds 2 cm. of soft tissue to the clinical intertuberos diameter of 8.6 to 9 cm., making it 10.6 to 11 cm., we were correct in slightly over 20% of the cases. This indicates that we were inaccurate in our clinical measurements.

We next examined the sum of the intertuberos and posterior sagittal diameters as determined by x-ray measurements. Figure 2 gives a much more satisfactory curve and indicates that, if we were able to measure the outlet more accurately, the sum of the intertuberos and posterior sagittal diameters might possibly be used as a prognostic yardstick. However, since we cannot, we have been forced to abandon it for determination of the method of delivery. We use it only for gross screening purposes.

It is generally believed that the intertuberos and posterior sagittal diameters are good prognostic criteria and that the anteroposterior diameter of the outlet (A. P. O.) plays a minor role, if any, in outlet contraction.⁶ Our British friends do not agree with those of us in America who use the intertuberos and posterior sagittal diam-

eters. As Moir,⁷ Williams and Phillips,⁸ and Morris⁹ of England recommend the anteroposterior diameter alone or combined with the interspinous diameter and subpubic angle, the anteroposterior diameter was examined next. Figure 3 shows a much more desirable curve. This

Fig. 1.—Per cent of difficulty in delivery based on sum of clinical measurement of intertuberos and posterior sagittal diameters.

curve is of value prognostically, since there is a definite break. The borderline diameter may be considered to be 10.5 cm. Unfortunately we do not have sufficient material to test the clinical anteroposterior diameter, but we suspect that it would not be very accurate, since in all

Fig. 2.—Per cent of difficulty in delivery based on sum of x-ray measurement of intertuberos and posterior sagittal diameters.

Because clinically it has been impossible for us to determine whether a difficult delivery in the low pelvis was due to the midplane, the outlet, or both, the interspinous diameter was tested (fig. 4). The interspinous of the midplane is a much more desirable curve than the outlet sum, but not quite so definite as the anteroposterior, although quite satisfactory. The critical diameter may be considered to be the 9 cm. level. This suggests that in many instances when we were under the impression that the obstruction was at the outlet, the actual disproportion was at least in some way concerned with the midplane.

This analysis has left us with three impressions. First, the use of the roentgenographic anteroposterior diameter will give a better yardstick to measure outlet contraction than the usually accepted criterion of the sum of the intertuberos and posterior sagittal diameters. Second, for practical clinical purposes, the midplane and the outlet should be considered as one plane. Certainly from an anatomic viewpoint these two planes can be separated

Fig. 3.—Per cent of difficulty in delivery based on x-ray measurement of anteroposterior diameter.

easily. When one manages the patient, however, the two planes cannot be separated. This latter conclusion was reached because of two facts (1) that the interspinous diameter gives a much better statistical criterion than do the intertuberos and posterior sagittal diameters and (2) that when the difficult midplane deliveries are added to the above material the character of the graph does not change (fig. 5). The third conclusion is that, since there is no absolute level with any yardstick in which an uninjured infant can be delivered vaginally, it must follow that by neither clinical nor roentgen examination can one predict vaginal or abdominal delivery, so the decision for doing an elective cesarean section on a vertex presentation without labor is not justified.

9. Morris, W. I. C.: Obstetrical Evaluation of Pubic Arch: Clinical Method, Lancet 2: 139, 1948.

the clinical measurements that we have tested, including the diagonal conjugate, the results were too inexact to be practical. We are, therefore, forced to accept the anteroposterior diameter as the best roentgenologic measurement for prognostication at the outlet.

TREATMENT

We have followed this type of management in patients with suspect midplane and outlet diameters. When there is an abnormal presentation, such as a breech, the decision must be made before labor, and in making that decision the general pelvic contour, pelvic measurements, and general fetal size must be taken into consideration. In vertex presentations we await the spontaneous onset

Fig. 4.—Per cent of difficulty in delivery based on x-ray measurement of interspinous diameter.

of labor. Antibiotics with a wide range are given, since at that moment we do not know how long the labor will be or whether the patient will be delivered abdominally. If true inertia develops, and there must be dilatation and effacement of the cervix for that diagnosis to be made, cesarean section is the procedure of choice. If normal contractions ensue, full dilatation of the cervix may be expected within a reasonable time. If there is normal descent in the second stage of labor, a spontaneous or easy low forceps delivery may be expected. If the presenting part fails to descend during the second stage of labor to bulging of the perineum, a trial of forceps delivery is made. If there is descent with gentle traction, vaginal delivery is consummated. If there is lack of descent with gentle traction and *vis-a-tergo*, we do not hesitate to deliver the patient abdominally through a laparotrachelotomy incision or by the extraperitoneal route.

In order for this type of management to be acceptable, we must deliver as many infants vaginally as possible, but without injury, and that includes those infants who leave the hospital alive. We had the following results before this line of management was followed, and we felt obligated to perform vaginal delivery when forceps blades were applied. These cases must include all patients regardless of the weight of the fetus. From July 1, 1947 to Aug. 1, 1951, we had 1,189 cases of vertex delivery in which x-ray pelvimetry had been obtained. Of those, forceps were indicated in 292 cases of which 177 were

easy forceps deliveries and 107 were difficult. There were seven cesarean sections done without attempts at vaginal delivery, and one cesarean section was performed after forceps failure. The fetal death rate was 4.5%, with an additional five infants injured. We have included shoulder dystocia because in each of these there was excessive traction necessary on the forceps to deliver the head. After delivery of the head, shoulder dystocia was recognized.

In the group of patients in whom we did not feel obligated to perform vaginal delivery after application of the forceps, there were 133 indicated forceps deliveries in 810 vertex deliveries. Seventy-nine women delivered easily vaginally, and 49 with difficulty vaginally. There were five patients in whom use of forceps failed and in whom cesarean section was done. There were no fetal deaths. Four infants were affected, but were discharged alive; two had intracranial hemorrhage and two had shoulder dystocia.

In the first paper¹⁰ on this subject Dr. Douglass and I did not include the easy low forceps deliveries that we encountered, and we used only the midforceps and difficult low forceps. This, we feel, was in error and are attempting to correct this mistake at this time. We are not convinced that this is the ultimate answer to this problem because (1) some inexperienced operators will, without a doubt, use too much traction; (2) there must be some infants who receive intracranial damage before attempts at delivery due to excessively potent uterine contractions and variations in each infant's ability to mold without

Fig. 5.—Per cent of difficulty in delivery with low forceps (and midforceps) based on x-ray measurement of interspinous diameter.

intracranial damage; and (3) the diagnosis of shoulder dystocia in these difficult vertex deliveries is extremely difficult before the head is delivered, although we should reevaluate fetal size when the pelvis does not seem too contracted and the forceps traction is not easy. However, we are sufficiently impressed with our reduction in fetal mortality with this group of patients at this time to continue with the trial forceps in practice.

SUMMARY AND CONCLUSIONS

1. The anteroposterior diameter of the outlet measured by x-rays is a superior method of prognostication of difficult delivery than either the clinical or x-ray sum of the intertuberos and posterior sagittal diameters in suspect outlets.

2. From a practical, clinical viewpoint, the midplane and the outlet should be considered one plane.

3. The trial use of forceps is recommended in patients in whom there is lack of descent during the second stage of labor. If gentle traction and correction of any unfavorable presentation, such as occiput transverse or occiput posterior, does not easily consummate delivery, cesarean section is a better procedure than vaginal delivery for the sake of the infant.

CLINICAL EVALUATION OF PRIMIDONE (MYSOLINE), NEW ANTICONVULSANT DRUG

Daniel Sciarra, M.D., Sidney Carter, M.D., Carmine T. Vicale, M.D.
and
H. Houston Merritt, M.D., New York

An appreciable number of patients with seizures are not helped by the standard anticonvulsants. There is, therefore, a constant search for new agents that will benefit this group. A new synthetic compound, primidone (Mysoline), has been made available to a number of investigators, and the results of four separate clinical trials had been reported at the time of writing.¹ Handley and Stewart^{1a} found this drug to be effective in 80% of 40 patients with grand mal seizures. In Butler's series^{1b} of 58 patients with all types of seizures, there was improvement in 50% of patients with grand mal attacks. Smith and McNaughton^{1c} were able to evaluate the results of primidone therapy in 61 patients and found that 35% were improved. Bonkalo and Arthurs^{1d} reported on the use of primidone in the treatment of epileptic and non-epileptic psychiatric patients. They noted a reduction in the seizure frequency in all of their 10 patients with clinical epilepsy. In the fall of 1951, primidone was made available to us for clinical trial. Since that time this drug has been administered to 121 patients, and the results of its use are the subject of this report.

CHEMISTRY AND PHARMACOLOGY

Primidone (5-phenyl-5-ethylhexahydropyrimidine-4,6-dione) is a compound closely related to phenobarbital. Basically, it is a reduced form of phenobarbital as a comparison of the two structural formulas indicates. Pri-

5-ethyl-5-phenylbarbituric acid (phenobarbital), figure on the left, and 5-phenyl-5-ethylhexahydropyrimidine-4,6-dione (primidone), figure on the right.

done is reported to compare favorably with phenobarbital, diphenylhydantoin (Dilantin), 3-methyl-5, 5-phenylethylhydantoin (Mesantoin), trimethadione (Tridione), and phenacemide (Phenurone) in abolishing the extensor tonic component of electrically induced convulsions in rats. The results were similar in pentylenetetrazol-induced convulsions in rats. In acute and chronic toxicity studies in animals, primidone was found to be relatively free of serious side-effects when given in amounts exceeding the recommended therapeutic dosage.²

CASE MATERIAL AND METHOD

The 121 patients in this series were for the most part those whose seizures had proved resistant to the standard anticonvulsants. Their ages ranged from 5 to 71 years, with the majority of patients in the age group from 20 to 40. Sixteen patients in this series were considered to have symptomatic epilepsy because of evidence suggesting the presence of gross neurological deficit. The remainder (105) were classified as having epilepsy of undetermined origin (idiopathic epilepsy). All seizure types were represented, but grand mal predominated either alone or in combination with one or more other types. In every case primidone was added to the medicaments that the patient was already receiving. The drug was supplied in tablets of 0.25 gm. each. The usual starting dosage of primidone was 250 mg. daily. This was increased one tablet daily at approximately weekly intervals to the point of therapeutic or toxic effect. If toxic manifestations appeared as the primidone dosage was increased, reduction of dosage of other anticonvulsants was usually carried out. Patients were seen at intervals ranging from one to four weeks. For the first year of this investigation, a routine blood cell count was done at each visit and later at longer intervals. Urinalyses were not done routinely but in a "spot check" manner.

RESULTS

The therapeutic effects could be evaluated in 72 of the 121 patients to whom primidone was administered. This group was followed for periods ranging from 1 to 18 months. The period of observation was 1 to 11 months for 28 patients and 12 to 18 months for 44 patients. In the remaining 49 patients, it was not possible to estimate anticonvulsant effect accurately, because administration

had to be halted after the appearance of toxic reactions or because follow-up data were inadequate or unreliable.

The attacks were entirely controlled in 7 patients (10%), reduced in frequency in 31 patients (43%), and unchanged in 34 patients (47%). Beneficial effects were obtained in 33 of the 50 patients with grand mal seizures (66%); in 10 of the 15 patients with psychomotor attacks (66%); in 11 of 21 patients with abortive or fragmentary types of grand mal, the so-called minor seizures (52%)³; and in 6 of 13 patients with focal seizures (46%). No benefit was noted in the six patients with petit mal. Sixteen of the 121 patients had seizures satisfactorily proved to be a symptom of gross organic brain disease. The therapeutic results could be evaluated in 14 of these, 5 of whom were benefited by therapy with primidone. The dosage of primidone ranged from 0.25 to 2 gm. daily in 72 patients in this study. Approximately one-third of the patients received less than 1 gm. of primidone daily; the other two-thirds were given from 1 to 2 gm. daily. The number of patients who received primidone in each of the doses listed is shown in the following tabulation, with the numbers of patients on the left and daily doses in grams on the right:

SIDE-EFFECTS OF PRIMIDONE

The incidence of side-effects resulting from primidone as administered in this study in conjunction with one or more of the standard anticonvulsants could be evaluated in 79 of the 121 patients. One or more side-effects appeared in 65 of these 79 patients (82%). No serious toxic reactions were observed. Routine blood cell counts remained normal in all cases. Drowsiness was by far the most frequent complaint, occurring in 54 patients. Ataxia developed in 18 patients. Five patients complained of mental dulness, and each of the following symptoms appeared only once: edema of the eyelids, painful gums, anorexia, irritability, excessive fatigue, and sexual impotence. Drowsiness was characterized by a variety of terms by the patients and ranged in degree from mild and tolerable to severe and irresistible somnolence. Ataxia in most of the cases consisted of unsteadiness in walking; in one case this was accompanied by nystagmus and slurred speech. Dizziness was the complaint of two patients, and two reported that they felt "groggy."

Administration of primidone had to be discontinued in 25 patients because of the severity of the side-effects, even though 4 of these had improved. Toxic symptoms disappeared or subsided sufficiently in 18 patients when dosage of the other anticonvulsant medication was reduced. In this group, when drowsiness was the complaint, the other anticonvulsants were usually of the sedative variety, namely, phenobarbital, mephobarbital (Mebaral), and Mesantoin. In four instances in which ataxia was

noted, improvement occurred when the dose of diphenylhydantoin was reduced. In 11 patients the toxic manifestations entirely disappeared upon reduction of primidone dosage. The degree of toxicity was so mild in four patients that it could be tolerated. In one patient the side-effects were transitory, and no change in dosage of primidone or other medicament was necessary. In a third of the patients side-effects developed with a daily dose of 0.75 gm. or less, and two-thirds of the patients manifested side-effects with a daily dose of 1.25 gm. or less. In the remainder, the toxic manifestations appeared when the daily dose exceeded 1.25 gm.

COMMENT

The majority of patients with epilepsy that is resistant to therapy are usually maintained on a combination of anticonvulsant drugs. It is the practice of this clinic in administering a new compound to add it to the preexisting regimen of medication. In all but 7 of the 72 patients in whom the therapeutic results were evaluated, primidone was given in conjunction with other drugs. Unless toxic symptoms appeared, no attempt was made to reduce the patient's other medication. The results, therefore, reflect the anticonvulsant effectiveness of primidone when used in conjunction with one or more of the standard antiepileptic medications. Of the seven patients with completely controlled seizures, six were taking, in addition to the primidone, diphenylhydantoin alone or diphenylhydantoin in combination with phenobarbital, Mesantoin, or mephobarbital. The seventh patient was taking mephobarbital in addition to the primidone. In the improved group of 31 cases, the additional drugs were as follows: diphenylhydantoin, 10 patients; diphenylhydantoin and Mesantoin, 5 patients; diphenylhydantoin and phenobarbital, 4 patients; diphenylhydantoin and mephobarbital, 2 patients; diphenylhydantoin, Mesantoin, and phenobarbital, 1 patient; diphenylhydantoin, mephobarbital, and phethenylate, 1 patient; phenobarbital and Mesantoin, 2 patients; phenobarbital, 1 patient; and mephobarbital, 1 patient. Of the seven patients to whom primidone was given alone, four were improved and three were unimproved.

The results of this study indicate that primidone is the most effective in the treatment of grand mal, psychomotor, focal, and minor seizures. Although the number of patients with symptomatic epilepsy in this series is too small to be statistically significant, the therapeutic results may indicate that primidone will provide some benefit for a small percentage of patients with seizures in this category. The dosage of primidone would not seem to be a factor in the unimproved group in that 25 of the 34 unimproved patients took 1 gm. or more daily, while in the benefited group of 38 patients, 16 took less than 1 gm. daily and 22 took 1 gm. or more daily.

The incidence of side-effects (82%) is unusually high; however, no serious toxicity was encountered. None of the patients manifested any evidence of depression of bone marrow activity or of renal damage. The single instance of edema of the eyelids was found not to be of renal origin; moreover, all but seven of the patients in this study were taking other compounds in maximally tolerated dosage when the administration of primidone was begun, and for 18 patients the reduction of the dos-

3. Sciarrà, D.; Carter, S., and Yahr, M.: Minor Seizures, *Tr. Am. Neurol. A.* 70: 253, 1951.

age of one or more of the other medicaments resulted in the disappearance of side-effects. The fact remains, however, that it was necessary to discontinue administration of the drug in 25 of the cases in which toxicity developed and that toxic manifestations appeared in 5 of the 7 patients receiving primidone alone. One patient attempted suicide by taking 25 tablets of 0.25 gm. of primidone (6.25 gm.) in one dose. The only effect was a deep sleep of four to five hours' duration. No special measures of resuscitation were required.

SUMMARY

A new compound, primidone (Mysoline), was administered to 121 patients with one or more types of convulsive seizures. Its anticonvulsant effect could be evalu-

ated in 72 patients who were observed for periods ranging from 1 to 18 months. In all but seven, primidone was given in conjunction with one or more of the standard anticonvulsant drugs. Seizures were completely controlled in 10%, reduced in frequency in 43%, and unchanged in 47%. The greatest benefit occurred when the seizures were of the grand mal, psychomotor, minor, or focal types. No improvement was noted in any of the patients with petit mal. Side-effects occurred in 65 patients, but none were serious. Drowsiness and ataxia were the two most frequent symptoms and made it necessary to discontinue the administration of primidone in 25 patients.

DIAGNOSIS AND TREATMENT OF ENCRUSTATIONS IN THE TRACHEA

THEIR RELATION TO RADICAL SURGERY OF THE HEAD AND NECK

John J. Conley, M.D., New York

Encrustations of the trachea as a complication of radical surgery of the head and neck have proved to be a serious and demanding problem in some instances. These encrustations are associated with the postoperative changes occurring in patients who have been subjected to tracheostomy. They impose an embarrassment to his respiration and indeed may precipitate asphyxiation and death. Care and prevention require diligent and aggressive supervision.

INCIDENCE

The incidence of encrustations of the trachea is not great. Approximately 10% of all patients who underwent resections requiring a temporary or permanent tracheostomy have postoperative encrustations to some degree. In only 2% did encrustations develop that were occlusive in size and capable of precipitating a dramatic airway block (fig. 1). If one is not alert to this problem and has not instituted prophylactic measures, the incidence may be higher. The vast majority of these cases occurred during the winter months. There was a definite relationship of the incidence of encrustations to the length of time the tracheostomy tube was permitted to remain in position. No encrustations were found in persons who wore a temporary tracheostomy tube for one to three days. The highest incidence of encrustations in the trachea was found in patients who wore the tracheostomy tube between the 3rd and 10th postoperative days. The incidence decreased after two weeks of tracheal intubation.

ETIOLOGY

Etiological factors contributing to the development of encrustations of the trachea may be divided into the intrinsic factors and the extrinsic factors. Although the intrinsic factors are more important than the extrinsic factors, it is the management and control of both of these situations that leads to the best therapy.

Intrinsic Factors.—Pulmonary Conditions: Any pulmonary condition that interferes with normal respiratory physiology contributes to the formation of encrustations.

Emphysema, bronchiectasis, chronic lung abscess, bronchitis and chronic lung disease fall into this category.

Tracheal and Bronchial Abnormalities: Any alteration in the respiratory epithelium of the trachea or bronchi is conducive to the formation of crusts. Intrinsic changes encountered in scleroma, fibrosis, atrophy, chronic infection, and metaplasia, and after irradiation over the trachea are all contributory factors.

Upper Respiratory System: Chronic or acute disease of the nasal cavity, sinuses, and pharynx associated with purulent postnasal drip into the trachea can affect the mucosal elements of the tracheal and bronchial tree. Thus these factors contribute to crust formation.

The Operative Area: The operative area includes the tracheostomy wound and also the major operative wound of the head and neck system that necessitated the tracheostomy. A purulent, infected discharge from the tracheostomy wound or operative wound that enters the trachea through the tracheostomy opening predisposes to the formation of crusts. A similar situation is created by the entrance of a purulent discharge from the operative wound into the trachea via the pharynx and larynx.

General Status of Patients: Major systemic disease that causes alterations in metabolism and electrolyte balance may be associated with dehydration, fever, and hyperpnea. These conditions predispose to the formation of crusts.

Extrinsic Factors.—Air Environment: Low humidity, particularly when associated with the drying effect of radiator heat in the patient's room during the winter months is conducive to the formation of tracheal crusts. A striking reduction in the incidence of this complication in the summer bears out the importance of this single factor.

Trauma: Trauma to the trachea caused by the irritation of the tracheal tube, excessive coughing, and frequent insertions of a catheter tip for tracheal irrigation all con-

tribute to tracheal encrustation. Such trauma should be avoided.

Infection: The lower respiratory system of the patient with a tracheostomy is constantly exposed to secondary infection. Such infection may be introduced from the catheter tip, from the hands of the attending nurse, from the insertion of tracheostomy tube, and from the unhygienic condition of the bedside table that holds the section catheter, the water for flushing it out, and the other accessory equipment.

Fig. 1.—A 6 cm. crust coughed out through a tracheostomy tube on the 11th postoperative day.

Bacteriology: One might presume that a single pathogenic organism could be consistently cultured from the tracheal secretions. This has not been the case, and cultures have produced a variety of common and ubiquitous gram-positive and gram-negative organisms. The predominant organisms have been *Pseudomonas aeruginosa*, *Staphylococcus aureus*, beta and gamma *Streptococcus*, *Staphylococcus albus*, diphtheroids, *Escherichia coli*, *Aerobacter aerogenes*, and bacteroids. The absence of anaerobic and hemolytic organisms was curious. No investigation was made for virus infection as an etiological factor, but it is doubtful if it is significant.

The etiological picture appears to be a composite one, with combinations of intrinsic and extrinsic factors altering the basic physiology of the tracheal mucosa. Multiple contributory factors predispose to development of crusts in the area, but the actual destruction of the ciliated, columnar epithelium by bacteria and toxins permits the crusts to form. The mucous blanket becomes stationary. Additional secretions and discharge are deposited on this dehydrated layer. An enlarging, thick, heavy crust of fibrin, cellular material, and debris expands along the trachea, and all normal local physiological processes cease (fig. 2).

DIAGNOSIS

The greatest advantage in making the diagnosis is an awareness of the possibility of tracheal encrustations in all patients with tracheostomies and the probability of crust formations in persons afflicted with predisposing etiological conditions.

If the encrustation is small, there are frequently no clinical symptoms. The patient, however, may experience the sensation that he desires to cough up something in the

trachea. In the incipient stages of crust formation the tracheal mucus is usually abundant, tenacious, and purulent in character. It may also be blood streaked. As crust formation begins, the mucus becomes thicker and less abundant. As the crust becomes larger, the mucus is frequently obstructed and cannot be aspirated; then when the crust is removed a considerable amount of tenacious mucus is subsequently aspirated by the catheter.

Auscultation of the chest may be helpful in encrustations that cause a whistling or obstructive musical sound in the trachea or bronchi. Again small encrustations frequently produce no abnormal auscultatory phenomena. Large obstructive encrustations may cause complete obstruction with atelectasis in the terminal or large bronchi.

The diagnosis of large tracheal encrustations is usually not difficult. There is almost always a history of the patient's having coughed out smaller scabs on multiple occasions. The normal clinical improvement is often interrupted with dramatic episodes of coughing out large tracheal scabs that may or may not come through the tracheostomy tube with forceful expiration. X-ray study of the trachea during this phase may reveal the irregularity of the lumen due to infringement by the expansion of these scabs.

Perhaps the greatest information concerning the trachea can be obtained by personally inserting the catheter tip repeatedly into the trachea in an exploratory

Fig. 2.—Drawing of encrustations on the tracheal wall. The inserts show the process of obliteration of the ciliated columnar epithelium and formation of lateral and concentric crusts.

and diagnostic maneuver. If obstruction is met anywhere along the course of the trachea or bronchi, then the diagnosis of tracheal encrustation may be made. On the other hand, passage of the aspirating catheter without meeting obstruction does not necessarily mean the absence of crusts, as the catheter can easily pass alongside of a quadrilateral crust or down the center of a concentric crust without difficulty. The commonest sites for catheter obstruction to be encountered are just beneath the tip of

the tracheostomy tube and at the level of the coryna. Frequently the act of inserting the catheter itself plus the violent cough reflex is enough to dislodge the tracheal scab. If it is of small diameter, it can be aspirated through the tracheostomy tube or coughed through the tube as a hard plug. If it is larger than the diameter of the tracheostomy tube, a characteristic wheezing and whistling type of respiration sets in with a bivalve phenomenon of alternate airway obstruction and relief with expiration and inspiration. This clinical situation always causes the patient extreme apprehension and excitement.

In a patient who has received inadequate postoperative aspiration and who has had excessive amounts of cough sedation, the tracheal scab may assume large proportions with complications. Atelectasis, pneumonia, air hunger, stridor, cardiac failure, or the total occlusion of the trachea or tracheostomy tube by a large encrustation may prove fatal. When the diagnosis has been unverified by previous clinical maneuvers and one is still suspicious of tracheal encrustations, a direct bedside bronchoscopic examination should be carried out for definitive information. When present they reveal a characteristic partial occlusion of the tracheal or bronchial air passage by an irregular hard dark crust. The mucosa beneath this scab is thickened, injected, and edematous, and is covered with a thin purulent exudate.

TREATMENT

The treatment of encrustations of the trachea is divided into the prophylactic and curative phases. The prophylactic phase begins with the anticipation of the formation of encrustations by careful evaluation of the predisposing intrinsic and extrinsic factors and the application of all measures to mitigate their effect. The surgeon can evaluate his patient and predict preoperatively with a great measure of success those persons in whom tracheal scabs are likely to form. This group consists of all patients with such predisposing conditions as emphysema, bronchiectasis, chronic lung abscess, bronchitis, and chronic lung disease. All tracheal and bronchial diseases characterized by intrinsic weakness of the respiratory epithelium secondary to chronic infection, scleroderma, fibrosis, atrophy, or intensive irradiation, predispose to scab formation. Other persons suffering from chronic sinusitis, pharyngitis, or purulent postnasal drip, have a predisposition to scab formation. All of these groups of patients are placed on a postoperative regimen that augments and favors lower respiratory function. They should receive adequate systemic biotherapy, aeropenicillin, frequent hygienic, atraumatic tracheal aspirations, and tracheal flushings with sterile saline solution four times a day; the humidity of the inspired air should be high. Special efforts should be made to prevent purulent discharge from draining into the trachea either through the tracheostomy opening or through the glottis. This is carried out by performing a circular excision of the tracheal cartilages in preparation for the insertion of the tracheostomy tube. This tube should fit snugly in the tracheal opening. The neck wound should be adequately drained away from the tracheal opening. All purulent secretions in the upper respiratory tract should be adequately aspirated.

If small encrustations of the trachea develop in spite of this regimen, aerosol trypsin (such as Tryptar) or detergents (such as Alevaire) should be incorporated into the program. They assist in dissolving crusts, thinning tenacious mucus, and clearing up the mucous membrane lining.

If large encrustations of the trachea develop, the situation becomes much more serious because of the danger of strangulation and the additional burden placed upon the heart, lungs, and major organs by chronic hypoxia. Often, the diagnosis of a large scab of the trachea is not immediately apparent. This is particularly true if the encrustation is concentric in form or if it is limited to one main bronchus just beneath the bifurcation. In these instances, the insertion of the aspirating catheter may meet with no obstruction and one may gain the impression that the trachea is clear. When these scabs become large enough, however, one encounters the serious signs of pulmonary obstruction, hyperpnea, stridor, tachycardia, hyperexcitability, and frequently atelectasis and bronchopneumonia. Encrustations that form in one or more quadrants of the trachea or bronchus (or bronchi) are frequently detected by causing an obstruction to the passage of the aspirating catheter. They should be softened with sterile saline solution and trypsin and dislodged with the aspiration catheter. In most instances, if they are not too large, they will be forcefully ejected with a strong expulsive cough through the tracheostomy tube. If the crusts are too large to come through the tracheostomy tube freely, the inner cannula should be removed after forceful cough with the hope that the encrustation will be withdrawn with it. If this is unsuccessful, the inner cannula is left out and the patient is encouraged to cough again.

If the encrustation is not extracted by these simple methods, the resident should remove the tracheostomy tube from the wound, and with the aid of aspiration, encourage the patient to cough forcefully. The encrustation may be coughed out through the circular tracheal wound or up into the mouth if it is not too large. If he has not been successful in removing the scab by this time, the patient should immediately undergo a bedside bronchoscopy with removal of the encrustation with an appropriate grasping forceps. The tracheal and bronchial trees then should be further inspected to rule out the presence of other encrustations. Bedside bronchoscopy, as an elective procedure, is desirable in the treatment of diagnosed concentric and large lateral crusts. When the clinical situation has become precipitant and bronchoscopy is not available, the surgeon may save the patient's life by inserting his finger into the tracheal opening and pushing the scab through the glottis into the pharynx.

The air environment should be highly humidified, and, if necessary, the patient should be placed in an oxygen tent where the local humidity can be more definitely controlled. The drying of air in the patient's room by radiators in the winter is a serious handicap. The use of a detergent or trypsin by nebulization is helpful in maintaining a high humidity and applying a crust and mucus digestant.

The trauma created by the insertion of the aspirating catheter should be kept at a minimum by using a no. 17 whistle-tip catheter that is inserted 6 to 8 in. (15 to 20 cm.) and then rotated between the thumb and index finger as the patient is encouraged to breathe deeply and cough. The patient should be turned from side to side so that both the left and right main bronchi may be aspirated.

There is no question that one of the precipitating factors to encrustation of the trachea is the repeated insertion of an unclean catheter that has been dragged all over the bed clothes and the bedside table, and perhaps has even fallen on the floor several times and is then fingered and wiped with unclean hands and tissues and finally irrigated in a basin of contaminated water. The repeated insertion of this bacteria-laden catheter with its associated trauma to the mucosa of the trachea and bronchi is often the precipitating factor in causing localized infection to the tracheal mucosa with the resultant destruction of the epithelium and the subsequent production of purulent exudate and scab formation. Therefore, great emphasis should be placed upon the hygienic methods of arranging and handling the suction apparatus.

The disappearance of these encrustations is quite characteristic. Large encrustations may persist for several days under the most energetic efforts to cure them. As the local tracheal mucosa begins to heal and the contributory etiological factors in the neck wound and oral cavity abate, the size and frequency of the occurrence of these scabs will gradually diminish. Their appearance will change from one or two very large and obstructing encrustations a day to perhaps five or six small scabs a day. With further improvement, the scabs will become smaller and less frequent in occurrence.

The most important single factor in eliminating encrustations is the return of respirations through the normal channels in the nose, pharynx and larynx. On the other hand, one hesitates to remove the tracheostomy tube of a patient who is forming extremely large encrustations in the trachea because of the danger of strangulation. In many of the radical procedures about the oral cavity, pharynx, mandible and tongue, a tracheostomy may be required for a period of one to two weeks or even longer. The ideal time for decannulation is when the encrustations have become small in size, the glottic and supraglottic airway are unquestionably adequate, and the patient is beginning to take nourishment by mouth without aspiration.

SUMMARY AND CONCLUSIONS

Encrustation of the trachea is discussed as a specific clinical entity in relation to tracheostomy. The association of this entity with radical surgery of the head and neck has given it added significance. The incidence of the condition and an analysis of the etiological factors indicate that the phenomenon develops from a composite situation associated with intrinsic biological factors and extrinsic physicoenvironmental factors. A careful evaluation of these factors mitigates the probability of crust formation. The importance of the effective control and treatment of this condition is emphasized by a shortened and improved convalescence and the diminution of the tragic danger of asphyxiation.

CLINICAL NOTES

INTESTINAL OBSTRUCTION DUE TO SWALLOWING OF AIR

REPORT OF A CASE

William Trevor, M.D., New York

The case to be reported of obstruction of the descending colon as a result of swallowing of air is of interest as I have been unable to find mention of a similar case in the world literature. Partial obstruction of the descending colon after swallowing of air by the patient over a period of several days was proved by roentgen-ray study with a barium enema. A total laryngectomy had been performed on this patient for cancer four years previously and, in order to speak, the patient used an esophageal voice necessitating the swallowing of quantities of air to be eructated so that the sound could be converted into speech by the lips, teeth, tongue, and palate. The mechanism of the obstruction can probably be explained by the fact that, owing to increasing distension of the proximal descending colon, the sigmoid folded over on itself near its peritoneal attachment, thus completing the mechanical intestinal obstruction.

A 60-year-old man was admitted to St. Clare's Hospital, May 2, 1951, with a chief complaint of having had no bowel movement for five days. The patient's daily bowel movements had been normal three weeks prior to his admission to the hospital, when he began a transcontinental motor trip; after this time the bowel movements became irregular. During the three days immediately preceding his admission, during enemas the water returned discolored at first but returned clear in four enemas the day before and in one on the morning he was admitted. Small amounts of flatus had been passed during this entire time. The day preceding his admission, his family physician administered neostigmine (Prostigmine) bromide; after therapy with this drug, a moderate amount of flatus was passed. The patient had never noticed any change in the caliber of the stool nor any evidence of bleeding from the rectum.

A total laryngectomy for carcinoma of the larynx with a permanent tracheostomy had been performed on the patient four years before. He had been trained to develop an esophageal voice by swallowing air into the esophagus and stomach and then belching the air forth when desiring to speak. At the age of 8, the patient had had rheumatic fever; except for this, his health had been good. Examination revealed a well-developed white man with a permanent tracheostomy in the suprasternal notch who spoke very well with an esophageal voice. The blood pressure was 180/80 mm. Hg and pulse rate 88. The abdomen was distended and tympanic, with no tenderness or rebound tenderness. Borborygmi were heard on auscultation. On rectal examination the rectal ampulla contracted around the examining finger.

The results of a complete blood cell count were within normal limits, the leukocyte count being 8,400, with a differential count of 62% segmented cells, 33% lymphocytes, and 4% monocytes. The electrocardiogram revealed a split P₂ wave compatible with mitral stenosis. Roentgen-ray examination by barium enema revealed the point of obstruction to be in the

descending colon with large gas-filled loops of colon and small intestine proximal to the point of obstruction (see figure).

Treatment consisted of continuous Wangenstein suction with a Miller-Abbott tube, Harris rectal flushes four times daily, complete restriction of oral intake, administration of fluids intravenously, and sedation. The use of suction on the Miller-Abbott tube withdrew large amounts of gas; the administration of the Harris rectal flushes caused expulsion of great quantities of flatus. During the first two days, a gradual de-

A, roentgen-ray film taken during barium enema showing point of intestinal obstruction in descending colon with proximal loops of intestine distended with air after prolonged swallowing of air. B, film taken after evacuation of barium enema showing markedly distended descending colon and small intestine proximal to the point of obstruction in the descending colon after swallowing of air.

crease in the degree of gaseous distension of the abdomen took place, and after five days the Miller-Abbott tube was withdrawn. The patient was discharged on the seventh day after his admission. Sigmoidoscopy, done as a follow-up study, revealed no abnormal condition, and the follow-up roentgen study by barium enema disclosed no abnormalities except a rather large descending colon.

160 East 74th St. (21).

ACUTE RETENTION OF THE FOLEY BAG CATHETER BALLOON

Henry Bodner, M.D.

Allan H. Howard, M.D.

and

Joseph H. Kaplan, M.D., Los Angeles

The Foley bag catheter, because of its simplicity, is an extremely valuable instrument for urologic purposes. However, the catheter has its trouble-making capacities. In addition to becoming obstructed, the balloon sometimes becomes exasperatingly difficult to deflate. The obstructive causes of bag retention are angulation, powder from gloves and other equipment, lint or cotton, blood clot, hemostatic crushing, or an imperfection (rubber flap over opening into the balloon or a bleb in the inflating tube) occurring in manufacture. To prevent such mishaps, one should test the catheter before using,

be certain catheters are not powdered and have not been stored with powdered goods, and instruct nurses to use fresh sterile water to inflate the balloon.

There are various means of deflating this catheter if difficulties should arise. It may be necessary to over-inflate the bag to the point of rupture. The 5 cc. bag frequently holds as much as 85 to 100 cc. of fluid before rupture, but in most instances 40 to 50 cc. of fluid is required. In the instance of hemostatic crushing, the inflating tube may be rolled between the fingers or the inflating tube and catheter may be cut off in sections until the urethra is approached. The injection of $\frac{1}{2}$ to 1 cc. of ether, xylene, or chloroform produces rupture of the balloon. The bladder must first be filled with fluid to dilute the irritating effects of the solvent.

To open up the obstructing rubber plug the ureteral catheter metal stylet may be passed along the inflating tube; the fluid will run out around the stylet. The metal stylet will not pass into the balloon itself because of the right angle opening of the inflating tube into the balloon. A Bugbee electrode may be passed alongside the catheter until resistance is felt against the overdistended balloon. The bladder should be filled with fluid and the fulgurating current turned on. This method is recommended for the 30 cc. balloon catheter, which may often be filled to 200 to 250 cc. before rupture will take place.

A whistle-tip ureteral catheter may be extended up to the balloon outside of the Foley bag catheter. Then a metal ureteral catheter stylet, previously measured, can be passed through the ureteral catheter to the balloon.

Another procedure involves cutting off the ends of the catheter and then passing a no. 28 F. resectoscope sheath over the catheter. A ureteral catheter metal stylet should be used inside of the resectoscope sheath and passed into the balloon. One may introduce a no. 16 F. or no. 21 F. cystoscope alongside a no. 24 F. catheter. The caliber of the catheter is compressed by the instrument. The balloon can be cut with a cystoscopic scissors or perforated with a rigid ureteral catheter metal stylet. A long thin needle passed through the abdominal wall and bladder just above the symphysis will perforate a balloon that has been distended to over 200 cc. of fluid. The 75 cc. bag may be distended in some instances to as high as 1,660 cc. before it will rupture.

When the catheter is removed, it should be inspected for missing pieces of rubber. One of our patients voided a piece of rubber nine months after a transurethral prostatectomy. The lost piece of rubber may be found in the dome of the bladder, since it floats on top of the urine or water. It is recommended that the manufacturers have two openings in the inflating tube into the balloon at the same site instead of in tandem. In the event one of the openings becomes plugged, drainage will be through the other opening. With the openings in tandem, if the distal opening becomes plugged, then the proximal opening of the catheter is not of any help. The opening into the balloon from the inflating tube if made at an angle may allow the passage of a ureteral catheter metal stylet into the balloon and thus make rupture of the balloon easy. A small pinpoint opening with slow deflation will be less apt to cause acute rupture with loss of the rubber in the bladder.

6333 Wilshire Boulevard (48) (Dr. Howard).

COUNCIL ON PHARMACY AND CHEMISTRY

NEW AND NONOFFICIAL REMEDIES

The following additional article has been accepted as conforming to the rules of the Council on Pharmacy and Chemistry of the American Medical Association for admission to New and Nonofficial Remedies. A copy of the rules on which the Council bases its action will be sent on application.

R. T. STORMONT, M.D., Secretary.

Methyletergonovine Tartrate.—Methergine Tartrate (Sandoz).— $(C_{20}H_{25}N_3O_2)_2 \cdot C_4H_9O_6 \cdot 2CH_3OH$.—M.W. 893.02.—N-[α -Hydroxy-methyl]propyl]-*d*-lysergamide tartrate containing two molecules of methanol of crystallization.—*d*-Lysergic acid-*d,l*-hydroxybutylamide-2 tartrate containing two molecules of methanol of crystallization.—The structural formula of methyletergonovine tartrate may be represented as follows:

Actions and Uses.—Methyletergonovine tartrate, a partially synthesized derivative of ergonovine maleate, is similar in action to the parent compound and other oxytocic alkaloids of ergot. See New and Nonofficial Remedies under the general statement on oxytocics and the monograph on ergonovine maleate.

Methyletergonovine tartrate induces uterine contractions in the immediate period after placental expulsion and in the puerperium by either parenteral or oral administration (within 30 to 60 seconds after intravenous injection, 2 to 5 minutes after intramuscular injection, and 3 to 5 minutes after oral administration). Clinical observations indicate that the intensity and duration of its oxytocic effect is somewhat greater than that of ergonovine maleate, but less prolonged than that of ergotamine tartrate.

Methyletergonovine tartrate is indicated for administration at the end of the third stage of labor or cesarean section to prevent or combat postpartum uterine atony and hemorrhage. It appears to have less tendency to produce pressor effects than does ergonovine and, therefore, may be suitable for use in the presence of preeclampsia or eclampsia. The drug also may be used to treat subinvolution and to combat secondary puerperal hemorrhage in conjunction with the removal of intrauterine clots. Its use in the presence of uterine infection is open to question.

Methyletergonovine tartrate is contraindicated during pregnancy and should not be employed routinely prior to delivery of the placenta; when used under full obstetric supervision, it may be given in the second stage of labor following delivery of the anterior shoulder. It shares the general toxic effects of ergot alkaloids that may result from overdosage or prolonged administration. Caution should be exercised in administering the drug to patients with sepsis and serious hepatic or renal involvement.

Dosage.—Methyletergonovine tartrate is administered orally, intramuscularly, or intravenously. Injection should be used immediately following delivery of the anterior shoulder or the placenta. A single dose of 0.2 mg. is injected intramuscularly or intravenously at the end of labor. If atony and hemorrhage persist post partum, further injections of the same dose may be given at intervals of 2 to 4 hours. A dose of 0.2 mg. may be given orally three or four times daily in treating subinvolution or during postpartum convalescence in place of the parenteral route.

Tests and Standards.—

Physical Properties: Methyletergonovine tartrate is a white to pinkish-tan, odorless, bitter, microcrystalline powder. It is very soluble in water, freely soluble in alcohol, and very slightly soluble in chloroform and in ether. Methyletergonovine tartrate must be protected from light and heat. The pH of a 0.02% solution is 5.0-5.8.

Identity Tests: Dissolve about 4 mg. of methyletergonovine tartrate in 6 ml. of water. The solution exhibits a bluish fluorescence under ultraviolet light. Divide the solution into two equal portions. To one portion add 2 ml. of a 1:1 mixture of glacial acetic acid and ethyl acetate. Stratify 2 ml. of sulfuric acid under the mixture: a bluish-purple ring appears at the zone of contact of the two liquids. To the second portion add 2 ml. of *p*-dimethylaminobenzaldehyde T.S.: a deep blue color appears.

The specific rotation, $[\alpha]_{25}^D$, of a 1% solution in water is +50 to +60°.

A 0.002% solution, prepared as directed in the spectrophotometric assay for methyletergonovine tartrate, exhibits an ultraviolet absorption maximum at about 310 m μ [specific absorbancy, $E(1\%, 1\text{ cm.})$, about 191], and a minimum at about 270 m μ .

Purity Tests: Dissolve about 0.25 gm. of methyletergonovine tartrate in 25 ml. of water. Add 5 ml. of diluted nitric acid and mix. Separate 10 ml. portions of the mixture yield no turbidity on addition of 0.5 ml. of silver nitrate T.S. (absence of chloride) and no turbidity on addition of 1 ml. of barium chloride T.S. (absence of sulfate).

Dry about 1 gm. of methyletergonovine tartrate, accurately weighed, in a vacuum desiccator over phosphorus pentoxide for 4 hours: the loss in weight does not exceed 5.0%.

Char about 0.5 gm. of methyletergonovine tartrate, accurately weighed, cool the residue, add 1 ml. of sulfuric acid, heat cautiously until evolution of sulfur trioxide ceases, ignite, cool, and weigh: the residue does not exceed 0.05%.

Assay: (Methyletergonovine Tartrate) Prepare a 0.002% solution of methyletergonovine tartrate as follows. **Caution:** Protect all solutions of methyletergonovine tartrate from light, preferably by using low actinic glass. Transfer to a 1,000 ml. volumetric flask 0.1 gm. of methyletergonovine tartrate, accurately weighed, fill to the mark with 1% v/v sulfuric acid, and mix. Transfer to a 100 ml. volumetric flask 20 ml. of this solution, fill to the mark with the 1% sulfuric acid, and mix. Spectrophotometrically determine the absorbancy in a 1 cm. quartz cell at 310 m μ , using 1% sulfuric acid as a blank. The concentration of methyletergonovine tartrate in the solution in mg./ml. = absorbancy $\div$ 19.1. The amount of methyletergonovine tartrate is not less than 95.0 nor more than 105.0%.

(Methyletergonovine) With the aid of 10 ml. of water transfer to a 125 ml. separatory funnel about 0.1 gm. of methyletergonovine tartrate, accurately weighed. Add 3 ml. of strong ammonia solution and 50 ml. of a saturated solution of sodium chloride. Extract the mixture with eight 25 ml. portions of ether. Collect the ether extracts in a 250 ml. beaker and evaporate them on a steam bath to about 2 ml. Add 25 ml. of 0.02 N sulfuric acid, accurately measured, and warm on a steam bath until the solids are completely dissolved and no odor of ether is detectable. Cool, add 20 ml. of water, and titrate the solution with 0.02 N sodium hydroxide, using bromophenol blue T.S. as an indicator. Run a blank titration using 200 ml. of ether. Each milliliter of 0.02 N acid consumed is equivalent to 0.006788 gm. of methyletergonovine and 0.008930 gm. of methyletergonovine tartrate. The amount of methyletergonovine is not less than 74.5 nor more than 77.5%, equivalent to not less than 98.0 nor more than 102.0% of methyletergonovine tartrate.

Dosage Forms of Methyletergonovine Tartrate

SOLUTIONS. **Physical Properties:** The pH of the solution is 3.5-4.5.

Identity Tests: The solution responds to the fluorescence and color identity tests for the active ingredient in the monograph for methyletergonovine tartrate.

The 0.002% solution prepared as directed in the assay responds to the spectrophotometric identity test for the active ingredient in the monograph for methyletergonovine tartrate.

Assay: (Methyletergonovine Tartrate) **Caution:** Protect all solutions of methyletergonovine tartrate from light, preferably by using low actinic glass. Transfer to a 100 ml. volumetric flask an amount of solution, accurately measured, equivalent to about 2 mg. of methyletergonovine tartrate, fill to the mark with 1% v/v sulfuric acid, and mix. Spectrophotometrically determine the absorbancy in a 1 cm. quartz cell at 310 m μ , using the 1% sulfuric acid as a blank. The concentration of methyletergonovine tartrate in the solution in mg./ml. = absorbancy $\div$ 19.1. The amount of methyletergonovine tartrate is not less than 95.0 nor more than 105.0% of the labeled amount.

TABLETS. **Identity Tests:** Transfer to a 125 ml. separatory funnel an amount of powdered tablets equivalent to about 4 mg. of methyletergonovine tartrate. Add 20 ml. of water and make the mixture alkaline to litmus with diluted ammonia solution. Extract the mixture with one 20 ml. portion of chloroform and filter the chloroform extract into a small evaporating dish. Evaporate the chloroform on a steam bath, and dissolve the residue in 6 ml. of water and 0.3 ml. of diluted hydrochloric acid. Filter the solution, if necessary. The solution responds to the fluorescence and color identity tests for the active ingredient in the monograph for methyletergonovine tartrate.

The 0.002% solution prepared as directed in the assay responds to the spectrophotometric identity test for the active ingredient in the monograph for methylergonovine tartrate.

Assay: (Methylergonovine Tartrate) Weigh 30 tablets and powder them. **Caution:** Protect all solutions of methylergonovine tartrate from light, preferably by using low actinic glass. Transfer to a 100 ml. volumetric flask an amount of powder, accurately weighed, equivalent to about 2 mg. of methylergonovine tartrate, add 50 ml. of 1% v/v sulfuric acid, and shake the flask mechanically for 15 min. Fill to the mark with the 1% sulfuric acid and mix. Centrifuge a portion of the mixture. Spectrophotometrically determine the absorbancy of the supernatant solution in a 1 cm. quartz cell at 310 m μ , using 1% sulfuric acid as a blank. The concentration of methylergonovine tartrate in the solution in mg./ml. = absorbancy $\div$ 19.1. The amount of methylergonovine tartrate is not less than 95.0 nor more than 105.0% of the labeled amount.

Sandoz Pharmaceuticals, Division of Sandoz Chemical Works, Inc., New York.

Solution Methergine Tartrate: 1 cc. ampuls. A solution containing 0.2 mg. of methylergonovine tartrate in each cubic centimeter.

Tablets Methergine Tartrate: 0.2 mg. U. S. patent 2,265,207. U. S. trademark 400,893.

COUNCIL ON PHYSICAL MEDICINE AND REHABILITATION

APPARATUS ACCEPTED

The following additional products have been accepted as conforming to the rules of the Council on Physical Medicine and Rehabilitation of the American Medical Association for inclusion in Apparatus Accepted. A copy of the rules on which the Council bases its action will be sent on application.

RALPH E. DE FOREST, M.D., Secretary.

Fortiphone Hearing Aid, Model 22

Fortiphone Limited, Fortiphone House, 247 Regent St., London, W.1, England.

Distributor: Anton Heilman, 75 Madison Ave., New York 16.

The Fortiphone Hearing Aid, Model 22, uses three vacuum tubes, one 1.5 volt mercury type A-battery, and one 30 volt B-battery. The body of the instrument measures 80 by 48 by 20 mm. and weighs, with batteries, 155 gm.

The Council secured evidence from acceptable sources indicating that the workmanship of the instrument was sound and that its performance was satisfactory.

Sonotone Hearing Aid, Model 977

Sonotone Corporation, Elmsford, N. Y.

The Sonotone Hearing Aid, Model 977, is a three tube instrument powered by one A-battery (1.5 volt mercury) and one B-battery (30 volt zinc-carbon). This instrument may also be used with a 22 volt B-battery and an adapter, as an alternative to the 30 volt battery. A choice of five receivers is offered. The total weight of the instrument with batteries, receiver cord, and receiver depends on this choice and ranges from 175.6 to 188.2 gm.

The instrument has a feature referred to either as a "self-control" noise suppressor, or automatic volume control (AVC). This volume-limiting control limits the maximum level of output to a choice of one of three levels regardless of the input.

Sonotone Hearing Aid,
Model 977

Evidence from acceptable sources indicated that the instrument was satisfactory in construction and operation.

Technicon-Huxley Chest-Abdomen Respirator Pump and Cuirasses

Conitech, Ltd., 215 E. 149th St., New York 51, N. Y.

The Technicon-Huxley Chest-Abdomen Respirator Pump and Cuirasses are intended for use in artificial respiration, particularly in poliomyelitis. The assembly consists of a set of four cuirasses, a power unit mounted on casters, and a flexible pipe or hose. The four cuirasses represent a range of sizes from child to adult. The edges of the cuirasses, which maintain air-tight contact with the patient's skin, are made of a spongy material resembling foam rubber. The pump is electrically driven, requires 60 cycle alternating current at 110 volts, and draws 175 watts.

The respirator is shipped in two crates, measuring 76 by 46 by 46 cm. (30¼ by 18½ by 18½ in.) for the power unit, and 64 by 45 by 69 cm. (25½ by 18 by 27½ in.) for the cuirasses. The former weighs 50 kg. (110 lb.); the latter, 23 kg. (50 lb.). Unpacked, the power unit measures 60 by 39 by 40 cm. (24 by 15½ by 16 in.) and weighs 43 kg. (95 lb.).

The frequency can be adjusted between 12 and 26 respirations per minute. The stroke volume is about 1,100 cc. Negative pressure can be controlled up to 40 cm. water; positive pressure can also be applied.

Evidence indicating sound construction and satisfactory operation was obtained from sources acceptable to the Council.

Technicon-Huxley Chest-Abdomen
Respirator Pump and Cuirass

Sonotone Hearing Aid, Model 1010

Sonotone Corporation, Elmsford, N. Y.

The Sonotone Hearing Aid, Model 1010, has two vacuum tubes, one transistor, a 1.25 volt A-battery, and a 15 volt B-battery. The body of the instrument, which is extremely thin, measures 76 by 43 by 15 mm. and weighs 75 gm. The two batteries weigh 23 gm., and the earphone with receiver cord weighs 11 gm., bringing the total weight to 109 gm. The Council obtained evidence indicating satisfactory construction and operation.

Sonotone Hearing Aid,
Model 1010

Normatone Hearing Aid, Model D-53

Johnston Hearing Aid Mfg. Co., 708 W. 40th St., Minneapolis 8.

Distributor: Normatone Hearing Aid Company, 22 E. Seventh St., St. Paul 1.

The Normatone Hearing Aid, Model D-53, has three vacuum tubes and is powered by two zinc-carbon batteries: an A-battery supplying 1.5 volts, and a B-battery supplying 22.5 volts. The body of the instrument is enclosed in a case made of a thermoplastic substance, measures 83 by 57 by 20 mm., and weighs 81 gm. With earphone, receiver cord, and the two batteries the total weight is 141 gm. There is no adjustable tone control and the volume control includes the off-on switch.

The Council obtained evidence indicative of satisfactory construction and operation.

Normatone Hearing Aid,
Model D-53

THE RABIES PROBLEM

An outbreak of rabies in Chicago has emphasized the importance of mustering all knowledge of the disease and its control for a realistic attack on the problem. Unfortunately it is commoner than generally believed. Furthermore, it is found in many animals other than dogs and foxes, including cattle, skunks, cats, horses, squirrels, sheep and other warm-blooded creatures.

Rabies is one of the oldest diseases known to mankind. It was mentioned in the Pre-Mosaic codes of Biblical peoples and described with amazing accuracy by Democritus, Aristotle, and Celsus. The causative agent was first found in the saliva of rabid dogs by Zincke in 1804, and a few years later Magendie and Bouchet were able to infect dogs with the saliva from human patients with this disease. The greatest contribution to the knowledge of rabies was the classical work of Pasteur with his famous nerve tissue studies and the modification of the virus by continuous passage, which led to the first effective vaccine.

Although the disease spread through every country of Europe in the 18th century, Norway, Sweden, Denmark, and the British Isles were able to eliminate the disease by ruthless sanitary measures, and importation quarantine enforcement has kept them rabies-free to this day. It was first recorded in what is now the United States in 1753 and soon spread westward with the growth of the nation. The disease is ubiquitous. Climate and season have no influence on its occurrence. It is found in the Arctic regions as well as the tropics of the old and new worlds. The infection depends entirely on the entrance of virus-laden saliva into a wound generally inflicted by the bite of the rabid animal. Attack rates in this disease depend on (1) the presence and amount of virus in the saliva of the biting animal; (2) the location of the bite on the body (bites around the head, neck, and face are the most dangerous; around the hands, feet, arms, and legs next in importance; and on the trunk least important); (3) the multiplicity of the bites; (4) the depth of the bite; and (5) the interposition of clothing. These factors should be considered in decisions on the intensity of vaccine treatment required. The rabies virus is an extremely labile organism and loses its virulence rapidly when exposed to light, heat, and drying.

Thus, fomites or indirect exposure by contaminated objects are of no real significance, because the virus is destroyed so easily in the atmosphere. The diagnosis is confirmed by the demonstration of Negri bodies in the brain of the suspected animal or by isolation of the rabies virus in the mouse after intracerebral inoculation of the mouse with emulsified brain tissue from the suspected animal. A recent advance in diagnostic techniques is the isolation of virus from the salivary glands. This procedure will indicate whether a bite has entailed a definite risk because rabies virus is shed in the saliva of only 50 to 75% of animals proved rabid.

On the basis of advances in rabies research, the World Health Organization (WHO) Expert Committee on Rabies has made some pertinent recommendations regarding the treatment of exposed persons as well as on the control of the disease. Bite wounds should be cleansed with soap or detergent solution. The use of strong mineral acids (e. g., nitric acid) may be resorted to in the case of a deep puncture type of bite wound that cannot be efficiently cleansed with soap or detergent solution. A review of indications for specific treatment with rabies vaccine is given in a chart prepared by the WHO Expert Committee dealing with intensity of treatment schedules based on the nature of the exposure and the clinical condition of the biting animal. In this connection, it is of paramount importance to capture and impound the biting animal for clinical observation whenever possible.

Antirabic inoculations are not without danger, and attention has been repeatedly called to the hazard of post-rabies vaccinal paralysis in children who are subjected to the heavy doses of antirabies vaccine required when face bites occur. Recently a report of 14,119 persons given vaccine for rabies in Hong Kong showed that only 17 suffered temporary paralysis of a muscle after the inoculations, or an incidence of 1.2 per thousand persons inoculated.

A new development in the specific biological treatment of exposed persons is the use of hyperimmune anti-rabies serum. Growing experimental evidence of the value of antirabies hyperimmune serum has prompted the committee to recommend that serum followed by the usual course of vaccine be used in cases of severe human exposure. One serum injection with 0.5 ml. per kilogram of body weight should be given within 72 hours of the bite or sooner. Hyperimmune serum is not yet available commercially, but some health departments have access to it on a field experimental basis.

Experience has shown that sound local rabies control programs should include the following minimum requirements: 1. Mass immunization of dogs. This should be carried out intensively on a schedule that aims at the vaccination of all owned dogs within the shortest possible time. In the face of a serious outbreak at least 70% of the entire dog population of the county should be vaccinated within a two to three week period. 2. Elimination of all stray dogs. Mass immunization will not reach the stray or ownerless dog, which remains as a potential threat in transmission of rabies. An efficiently conducted

program requires the operation of a local pound or humane shelter where stray animals may be kept for a few days and, if unclaimed at the end of that period, destroyed humanely. Collection of strays should be carried out by teams of dog wardens and assistants in properly equipped trucks. Licensing or registration of all dogs is an important adjunct of a successful program. If properly enforced, it identifies the ownerless strays, helps to defray the expenses of control activities, and assures a reasonably accurate dog census. 3. Reduction of excess numbers of wildlife vectors. Outbreaks of rabies in wild animals, particularly foxes, occur generally when the population of the species becomes particularly dense in an area. Organized county-wide trapping programs are the most effective means of reducing this overpopulation to a safe level in areas menaced by fox rabies.

Other important measures are restraint of dogs while the control campaign is under way and pursuit of a continual and energetic publicity campaign. Essential to the success of the program is good organization under health department and veterinary medical auspices, with the fullest use of all technical resources in the community. The most significant single advance in rabies control in the past few years is the successful use of canine prophylactic vaccination. Laboratory and field demonstrations have shown that mass immunization of dogs is an essential phase of a successful rabies control program. Recent experimental work has shown that live modified virus vaccine (Flury strain) prepared from chicken embryos produces superior immunity in dogs that lasts for at least three years after a single intramuscular inoculation.

PATHOGENICITY OF *ESCHERICHIA COLI*

Diarrhea in infancy is still an important cause of death in the first few weeks of life and is the scourge of hospital nurseries. In addition to the causes that have long been recognized, a great mass of evidence has been accumulating in recent years that would indicate that although most strains of *Escherichia coli* are harmless there are strains (notably 0111 and 055; others less frequently) that may cause severe diarrhea in infants and adults and in infants may even cause death.¹ This evidence at first was based on the finding that one of these strains predominated in the stools of the affected infants but not in those unaffected; that an outbreak coincided with the introduction into a nursery of organisms of the serogroups 0111 (or 055, 026, etc.) and ceased with the disappearance of this strain from the nursery. It is a characteristic of this disease that it is severe in the very young, is highly contagious, and tends to recur both clinically and bacteriologically.

In order to determine whether there was other than the epidemiological evidence mentioned for the pathogenicity of these strains of *Esch. coli* serological tests were made.² Since there was no antibody response in infants after an attack of diarrhea associated with strains 0111 and 055 in the stools, a hemagglutination test was developed and it was found that volunteers who ingested cultures of strain 055 responded with an increase in titer

of homologous *Esch. coli* hemagglutinin. These same volunteers did not show an increase in titer to heterologous *Esch. coli* hemagglutinin. Other volunteers acting as controls who ingested innocuous strains did not show any increase in titer of *Esch. coli* 055 hemagglutinin. In volunteers who ingested cultures of strains 0111 or 055 mild to severe diarrhea developed, but this did not occur in the control subjects. H as well as O strains of this serogroup should be included in epidemiological studies.^{1c}

The exact mode of transmission of this infection is not known. The presumably pathogenic strains have been cultured from feces, rectal swabs, nasopharyngeal swabs, furniture, towels, rubber nursing nipples, and the hands of nurses.³ Cross infection on wards has been observed frequently, and carriers have been found among adults. In one nursery in which an epidemic occurred it was found that the babies were taken to their mothers in a vehicle used by all, the bathing table was used in common by sick and well babies, and a common container held all the rectal thermometers.^{1d} More careful control of ward sanitation usually checks epidemics. Failure of these measures to do so may be due to inadequate control procedures or to a failure to attack the true mode of spread, which may be alimentary, respiratory, or both.³

Chlortetracycline, oxytetracycline, and chloramphenicol have been used successfully to suppress *Esch. coli* 0111 and 055 in the stools. This always leads to clinical improvement, thereby adding another link to the chain of evidence of the pathogenicity of these organisms.⁴ Chloramphenicol-resistant strains have been observed after treatment with this drug, and persons with cross infections in one study^{1a} were all found to harbor chloramphenicol-resistant organisms. On the other hand, neomycin was found to cure the infected infants in one epidemic without producing neomycin-resistant strains, and in this epidemic there were no deaths.

It may be concluded that epidemic diarrhea in infants is still a serious disease, which may be produced by a variety of organisms. There is strong evidence that certain serogroups of the usually innocuous *Esch. coli* may cause serious and even fatal disease in infants. The causative organism in epidemics of infantile diarrhea should be determined, and in such determinations the possibility that this may be a pathogenic strain of *Esch. coli* should not be overlooked.

ORGANIZATION SECTION

RHODE ISLAND MEDICAL SOCIETY

To permit readers of THE JOURNAL to become better acquainted with the activities of state medical associations articles describing them will appear from time to time in these pages.—ED.

The Rhode Island Medical Society was established in 1812. Dr. Robert Jeffreys, holder of the earliest license granted in Rhode Island, was in 1641 "authorized to exercise the function of Chirurgie." The first medical degree conferred in any of the colonies was that bestowed on Capt. John Cranston in 1664 by act of the colonial legislature, which reads: "Whereas the Court hath taken notice of the great blessing of God on the good endeavors of Captayne John Cranston of Newport, both in phissicke and chirurgery, to the great comfort of such as have had occasion to improve his skill and practice etc. The Court doe therefore unanimously enacte and declare that the said Captayne John Cranston is lycenced and commistioned to administer phissicke, and practice chirurgery throughout this whole Collony and is by this court styled and recorded Doctor of phissicke and chirurgery by the authority of this the Gen-

Headquarters of Rhode Island Medical Society.

eral Assembly of this Collony." During the following century, according to records uncovered by the late Dr. W. S. Sherman, Dr. William Hunter of Newport delivered in January and February, 1755, the first advertised public course of medical lectures given in the colonies. Shortly after the beginning of the next century, Rhode Island College, to which Nicholas Browne Jr. had given \$5,000, became Brown University and, in accordance with its charter rights, conferred the M.D. degree on Solomon Drowne. In 1811 its school of medicine was opened. Lacking endowment, library, laboratories, and clinics, it nevertheless had three professors, each with a chair of his own: Dr. Drowne, materia medica and botany; Dr. William Ingalls, anatomy and surgery; and Dr. William Corlis Bowen, "chymistry."

One year later the medical society, strongly advocated by these men and several of their contemporaries, came into being. Forty-nine men from all sections of the state signed the act of incorporation, and Dr. Amos Throop became the first president of the Rhode Island Medical Society. The largest number of founders came from Providence (14) and Newport (7), and these cities were designated as host to the annual meeting in alternate years. In "Early Medical History in Rhode Island and the Rhode Island Medical Society," the late Dr. Walter L. Munro pointed out: "The meetings were held at various places but especially in the Colony House at Newport and the old State House in Providence. There was, of course, a dinner or at least a luncheon. Going over the old records, one is led to infer that

the privilege of providing (and paying for) the banquet was one of the perquisites of the President in office. Dr. Eldredge hints delicately that it seemed to him at times that the attendance at the dinner was even larger than at the meeting." In 1846 the meetings became semiannual, the place of the midyear meeting being determined by vote, and in 1866 quarterly, the annual meeting being held in Providence in June.

In legislative and civic projects, in the furtherance of medicine and public health, the society has a brilliant history of achievement. In 1800 a Newport physician, Dr. Benjamin Waterhouse, introduced vaccination to this country, and 56 years later Dr. Edwin M. Snow made Providence one of the first cities in the United States to require vaccination against smallpox as a qualification for school enrollment. Dr. Levi Wheaton, a surgeon in the Revolutionary War, and Dr. Joseph Mauran, early presidents of the society, led the fight against Asiatic cholera, which first appeared in the United States in 1832, and it was through their efforts and the petitions of the society that Providence became one of the first cities in the nation to have a full-time superintendent of health. Dr. Usher Parsons, president of the society 1837-1840 and the only surgeon entrusted with the treatment of the wounded in Commodore Oliver Hazard Perry's naval battle at Lake Erie, initiated the movement that finally resulted in the erection of Rhode Island Hospital in 1868. In 1871, through the efforts of the society's legislative committee, the legislature passed the law requiring the examination and registration of pharmacists and creating the Board of Pharmacy, and 13 years later the society was instrumental in obtaining passage of the Medical Examiner Act, which did away with most of the abuses, inadequacies, and delays of the old coroner system. In the interim, long agitation by the society for a state board of health had finally culminated in success, and subsequently Rhode Island became the first state health department to undertake the work of free examination of sputum for the diagnosis of tuberculosis under the direction of the medical profession. In 1894, after a 16 year struggle, a law governing the registration of physicians and regulating the practice of medicine was passed—a crowning achievement for the society—and in 1885 a board of medical examiners was created, which provided adequate oral and written tests of the applicant's ability. Originating too in the Rhode Island Medical Society were such institutions as the sanatorium at Wallum Lake (1906), the School for the Feeble-Minded (1907), and the Providence City Hospital (1910).

A widely known project of the society is the annual competition for the Fiske Fund prize, established in 1835 by Dr. Caleb Fiske, fourth president of the society—country doctor, hospital surgeon, judge of the common pleas court, banker, and financier. Dr. Fiske provided that nine-twelfths of the income of the fund be devoted to a prize to be given annually to the best essay on a subject or subjects to be assigned by the trustees, and that two-twelfths be set aside as remuneration for the trustees, adding "And it is also believed that said trustees . . . will frequently, if not *uniformly*, render their service gratuitously, whereby a further addition may be made to said fund." Under this proviso the fund has increased many fold, and the prize, originally \$40, is now \$250.

Need for the headquarters of the society was felt long before the building itself materialized. The first donation toward a building fund, a gift of \$500, was made in 1882. In 1887 the General Assembly granted the right to hold property up to \$100,000 in value, but it was only when faced with the necessity of removing its books from the public library that the society was finally goaded into action. On June 1, 1911, 99 years after the founding of the society, the cornerstone was laid, and one year later the building was formally dedicated and opened with ceremonies at which Dr. Abraham Jacobi, President of the American Medical Association, gave the principal address. The

building, at 106 Francis St., Providence, was dedicated as a state medical library, owned and maintained by the society. Its 38,000 bound volumes and journals, in charge of a full-time librarian and assistant, are housed for reference by the citizens of Rhode Island. It has a fine reading room and an ample auditorium that serves as the meeting place for the society and for the Providence Medical Association. In July, 1942, the society created a central office at the Medical Library with a full-time executive secretary in charge. The *Rhode Island Medical Journal* has been issued under the direction of the society since 1917. Officers of the society are Dr. Earl F. Kelly, Pawtucket, president; Dr. Henri E. Gauthier, Woonsocket, president-elect; Dr. Herbert E. Harris, Providence, vice-president; Dr. Thomas Perry Jr., Providence, secretary; Dr. John A. Dillon, Providence, treasurer; and John E. Farrell, Sc.D., Providence, executive secretary. The approximately 800 members of the society represent seven constituent medical associations, which include the cities of Providence, Pawtucket, and Woonsocket, and the counties of Bristol, Kent, Newport, and Washington.

A. M. A. VIEWS ON H. R. 7341

February 3, 1954

The Honorable Charles A. Wolverton, Chairman
Committee on Interstate and Foreign Commerce
United States House of Representatives
Washington 25, D. C.

Dear Sir:

I would like to take this opportunity, on behalf of the American Medical Association, to submit for your consideration our views concerning H. R. 7341, 83d Congress, which is currently being studied by your Committee.

It is our understanding that this bill would amend the Hospital Survey and Construction Act, as amended, so as to provide assistance to the states in surveying the need for and in constructing diagnostic or treatment centers, hospitals for the chronically ill, rehabilitation facilities and nursing homes.

When the Hospital Survey and Construction Act, familiarly known as the Hill-Burton Act, was before the 79th Congress it was studied very carefully by the House of Delegates, the Board of Trustees and by several councils of the American Medical Association. As a result of that study, the intent and purposes of the legislation received our approval. The Association has continued to support the law since its enactment on August 13, 1946.

We are gratified to note that since the approval of the first projects in fiscal year 1948 approximately 50,000 hospital beds have been constructed under this program. In addition, approximately 45,000 additional hospital beds are now under construction. Apparently rapid progress has been made; projects have been allocated for areas where they are most needed and are being put into service with commendable promptness.

It appears from the language of the pending bill that the proposed extension of federal assistance to the states in connection with the construction of medical facilities other than hospitals will be experimental in nature. The definitions of "diagnostic or treatment centers," "rehabilitation facilities" and "nursing homes" contained in the bill are general in nature and will be subject to more definitive treatment through federal administrative regulations at a later date. These facts plus the lack of recognized standards for these facilities will place a serious responsibility upon the Department of Health, Education and Welfare to promulgate regulations which will preserve maximum local autonomy and administrative responsibility.

Our primary recommendations with respect to this measure are that facilities for the chronically ill and impaired should be part of, or near a conventional hospital and that the original purpose of the Hospital Survey and Construction Act be reaffirmed. As you know, the original Act of 1946 and the amendment of October 25, 1949, both emphasized that the purpose of the Act was to assist the states in providing hospitals and "similar services to all their people." We believe it is imperative that any facilities constructed under this proposal should also be available for the use and benefit of the entire community

rather than for any particular segment of the population. To insure this result it is our opinion that the original purpose of the Act should be restated.

The pending bill has not been officially considered by our House of Delegates or Board of Trustees; however, it does not appear that the proposed expansion of the program constitutes any fundamental change in the principles embodied in the existing law. I should like to urge therefore, on behalf of the American Medical Association, that the subject legislation be reported favorably by your Committee, subject to the amendments indicated.

Sincerely,

GEORGE F. LULL, M.D.
Secretary and General Manager.

THE SAN FRANCISCO MEETING

This year in San Francisco the annual meeting of the American Medical Association will be held from June 21 to 25. General meetings will occupy the program all of Monday and also Tuesday morning. One half of the sections will meet Tuesday, Wednesday, and Thursday afternoon and one half on Wednesday, Thursday, and Friday morning. All meetings except those of the ophthalmology section and the Wednesday evening meeting (to be held in the Terrace Room of the Fairmont Hotel) will be held in a group of buildings in the Civic Center. The Section on Miscellaneous Topics will include a session on legal medicine for the first time. The telecasting of clinics and operations will be in color, will originate in the San Francisco General Hospital, and will be shown on two 4 by 6 foot screens. The latest and best medical motion pictures will be shown throughout the week. Because of the success of the evening showing of motion pictures at the St. Louis meeting, the world premiere showing of some outstanding films of broad general interest (titles to be revealed later) will take place at the Wednesday evening meeting, with a discussion of each of these new films.

In the Scientific Exhibit in the Civic Auditorium there will be about 220 exhibits grouped according to the Sections of the Scientific Assembly. Features of outstanding interest will include special exhibits on fractures and blood banks. Among other special exhibits will be fresh pathology, sponsored by the Section on Pathology and Physiology; "Preceptorships in Undergraduate Medical Education for General Practice" by the Section on General Practice; and "Pulmonary Function Testing" by the Section on Diseases of the Chest. There will be a question and answer conference on cardiovascular diseases in cooperation with the American Heart Association and a "quiz corner" conducted by the editorial department of the A. M. A. where physicians may bring their problems to various experts in the different fields of medicine.

In the Technical Exposition about 400 firms will bring to the attention of physicians the latest developments in new drugs, books, and other adjuncts to the practice of medicine. A portico covering nearly 40,000 square feet will be erected over the street in front of the auditorium.

TELEVISION PROGRAMS

Dates for three new "March of Medicine" television programs have been announced by Smith, Kline and French Laboratories and the American Medical Association. The first program will be on March 11 over the National Broadcasting Company's television network; other programs will be on April 29 and June 24. Like the 1953 series, the new "March of Medicine" programs will be presented at 10 p. m. (EST), replacing the "Martin Kane" show usually seen at that time.

On March 11, "March of Medicine" will bring TV viewers up-to-date on the subject of overweight. The program will include scientific discussions on the cause of obesity and practical solutions to the weight-gaining problem. Arthritis and rheumatism is the topic for the April 29 show. Subject matter for the June 24 program, to originate from the American Medical Association's Annual Meeting in San Francisco, is still to be assigned.

REQUESTS FOR PLACEMENT AID

More physicians are utilizing the services offered by the A. M. A. Physicians Placement Service than ever before, reports the Council on Medical Service. A brief look at the number of services rendered by the Placement Service during the last three months of 1953 as compared with the same period of 1952 shows: (1) a 95% increase in the number of requests from communities seeking physicians; (2) a 130% increase in the number of letters of inquiry from physicians seeking places to locate; and (3) a 364% increase in the number of physician visits and personal interviews in the A. M. A. office. The A. M. A. Physicians Placement Service operates in close cooperation with the 43 state physician placement services.

QUARTERLY CUMULATIVE INDEX MEDICUS

Volume 51 of the Quarterly Cumulative Index Medicus, covering literature for the first half of 1952, has been mailed to subscribers and is now available for purchase from the Order Department of the American Medical Association. At present, volume 52 (covering literature for the period July-December, 1952) is in press, but it will not be ready for distribution for several months.

FEDERAL MEDICAL LEGISLATION

Appropriations for Office of Vocational Rehabilitation

Senator Kefauver (D., Tenn.) in S. 2837 proposes to amend the Appropriations Act of 1954 to delete the provision limiting the federal share to \$1 for each 75 cents contributed by the state for its Vocational Rehabilitation service. The bill was referred to the Appropriations Committee.

Federal Board of Hospitalization

Congressman Evins (D., Tenn.) proposes in H. R. 7474 to establish a Federal Board of Hospitalization, to be composed of seven government officials from various parts of the executive branch of the government. This board would study federal hospital activities and make recommendations (1) "To prevent overlapping, duplication, and overbuilding of such facilities; (2) to insure the most efficient and complete utilization of the total hospital, convalescent, and domiciliary facilities of the Federal Government by each department and agency; (3) to determine the need for existing or additional hospital, convalescent, and domiciliary facilities of each department and agency; (4) to determine the area and locality in which such additional facilities should be provided; (5) to determine the extent to which non-Federal facilities may be used to supply beds for any department or agency; (6) to develop a complete over-all plan relative to facilities for providing within or through the Veterans' Administration adequate hospitalization and domiciliary care for persons who have served in the Armed Forces of the United States; (7) to make studies and recommendations with respect to such matters as may be referred to the Board by the President, or by any member of the Board."

This bill, which is identical with H. R. 2862 (Rogers, Mass.) and similar to H. R. 633 and S. 1436 previously reported, was referred to the Veterans Affairs Committee.

Medical Committee on Alcoholism

Congressman Radwan (R., N. Y.) would establish in H. R. 7531 a medical committee on alcoholism to advise and cooperate with the U. S. Public Health Service in promoting education on alcoholism throughout the federal agencies, states, and educational bodies and advise on the establishment of clinics on alcoholism. This advisory committee would consist of 7 to 15 members, all physicians, who would be appointed by the President and would serve five year terms without pay. This bill was referred to the Interstate and Foreign Commerce Committee.

The summary of federal legislation was prepared by the Washington Office of the American Medical Association and the summary of state legislation by the Bureau of Legal Medicine and Legislation.

STATE MEDICAL LEGISLATION

Kentucky

Bills Introduced.—H. 290, proposes a Kentucky board of optometric examiners to provide for the regulation of the practice of optometry. H. 301, proposes the creation in the department of Kentucky state police of a bureau of criminal identification and statistics. S. 129, proposes that any physician licensed to practice medicine in Kentucky who is a member in good standing in the Kentucky State Medical Association and of the medical association of the county in which he resides or in which he practices shall be permitted to practice in any hospital totally or partially supported by public funds.

Massachusetts

Bills Introduced.—H. 2353, proposes the creation of a special commission to investigate and study the advisability of establishing a state medical and dental school under the jurisdiction of the University of Massachusetts. H. 2390, App. B, proposes to revive and continue the special commission established to make an investigation relative to the sale, furnishing, delivery, exchange, and use of narcotic drugs within the commonwealth.

Michigan

Bills Introduced.—H. 229, proposes to require every supervisor or laboratorian in charge of any laboratory registered with the Michigan department of health to give notice in writing of every positive laboratory test for communicable disease performed by said registered laboratory. H. 242, to amend the law relating to tuberculosis, proposes to authorize county probate courts to direct the isolation of persons suspected of having tuberculosis but who are unwilling to submit to an examination and to furnish specimens for laboratory study. H. 287, proposes to repeal the basic science act. H. 290, to amend the law relating to chiropractic, proposes to redefine chiropractic as being the diagnosis of human ailments and the prevention and correction of such ailments by the removal of nerve interferences and the adjustment of the spinal column and other joints and tissues, the procedure preparatory to and those common measures incidental to the prevention and correction of such ailments. This shall not be deemed to include the use of medicinal drug treatments or the practice of operative surgery or the practice of midwifery. The present law limits the activities of the chiropractor to hand manipulation. H. 412, proposes to authorize the Michigan department of health to establish, when necessary, reasonable standards of maintenance and operation for hospitals within the state and to provide for periodic inspections of the hospitals to determine whether or not they comply with the standards. S. 1166, proposes certain amendments to the law relating to osteopathy, chief among which is the substituting of the words "osteopathic medicine and surgery" for the word "osteopathy" in the present law, and also a rewording of the grounds for revocation of a license of an osteopathic physician or surgeon. S. 1255, proposes, among other things, to require every practicing physician who shall examine any person and find that such person is addicted to the use of narcotic drugs to make a report thereof to the health officer of the county, city, township, or district in which such person is a resident. S. 1257, proposes the creation of a Michigan commission on the aging to study and investigate the employment, economic, health, educational, recreational, housing, institutional care, and other needs of aged persons. S. 1258, proposes to amend the hospital survey and construction act by defining a hospital as including outpatient departments and mental rehabilitation and convalescent facilities in which patient care is under the professional supervision of persons licensed to practice medicine in Michigan.

Mississippi

Bills Introduced.—S. 1405, proposes the creation of a board of chiropractic examiners and defines chiropractic as the science, art, and philosophy of things natural; a system of locating and adjusting the subluxations of the articulations of the human spine and its adjacent tissues for the correction of the cause of disease. S. 1425, proposes regulations for the conducting of autopsies for the purpose of determining the primary and/or contributing causes of death in the interest of public health in criminal cases and other forensic cases of disease, or for the purpose of determining the extent of the diseased condition for scientific and/or statistical purposes. Under the proposal, any physician duly licensed by the Mississippi state board of health may perform an autopsy, but it is preferable that such person be certified in pathological anatomy by the American Board of Pathology.

New Jersey

Bills Introduced.—A.C.R. 11, proposes the creation of a joint commission to study the possible sources of funds for the proposed medical and dental college of New Jersey from foundations and other private sources. A. 44, proposes an appropriation to the department of institutions and agencies for the treatment of persons using narcotics. A. 56, to amend the workmen's compensation act, proposes that an injured employee may, when care is required, select to treat him any duly licensed physician and provides that if the employee is unable to make the selection for any reason, then the employer shall promptly provide him with the necessary medical care. A. 151, proposes to set aside the funds of the Veterans Loan Guaranty and Insurance Fund into a special fund to be known as the Medical and Dental College of New Jersey Fund to be used for the creation and establishment of a medical and dental college in New Jersey.

New York

Bills Introduced.—A.R. 78, proposes that the joint legislative committee make a survey and study of the social, educational, and physical problems of persons afflicted with cerebral palsy. A. 1369, proposes regulations for the compulsory care, treatment, guidance, and rehabilitation of narcotic drug users. A. 1381, proposes that membership corporations furnishing medical expense indemnity shall include podiatric care provided through duly licensed podiatrists. A. 1451 and S. 1182, to amend the law relating to health and welfare services for school children, propose that such services shall be available to all children attending school, whether such school be public or private. A. 1654 and S. 1356, to amend the education law in relation to prorated medical expense indemnity allowances, propose that nothing shall prohibit a medical expense indemnity corporation pursuant to its contract with the subscriber from prorating a medical expense indemnity allowance among two or more physicians in proportion to the services rendered by each such physician at the request of the subscriber, provided that prior to payment thereof such physicians shall submit both to the medical expense indemnity corporation and to the subscriber statements itemizing the services rendered by each such physician and the charges therefor. A. 1675, to amend the law relating to osteopathy, proposes that no person who is blind but otherwise qualified pursuant to the requirements of the law, shall be denied the additional rights provided for except that such additional rights shall not include the right to perform any act of surgery nor the right to administer drugs or anesthetics. A. 1685, proposes to prohibit a person from selling or offering to sell the eye of a human being during his lifetime and proposes that any contractual arrangement or understanding wherein or whereby the eye of a living or deceased human being is sold or offered for sale shall be deemed to be contrary to public policy. Nothing in the proposal would prohibit a person from donating, without fee, the eye of a human being during lifetime or prohibit any person from the right to direct the manner in which his body or parts of his body may be disposed of after his death. A. 1736, A. 1738, and S. 1466, propose the creation of a state board of chiropractic examiners and defines chiropractic as a system of therapeutics based on the premise that all physiological processes of the human body are coordinated by the nervous system; that interference with the nerve control of these processes impairs their function and induces disfunction or disease by rendering the body less resistant to infection or other exciting causes. Its therapy is designed to detect and correct by manual or mechanical means structural imbalance, distortion, or subluxation of the human body for the purpose of moving nerve interference, where such interference is the result of or related to distortion, misalignment, or subluxations of or in the vertebral column. A. 1768 and S. 1479, propose the creation of a temporary state commission to be known as the commission on licensure in the healing arts, for the purpose of making a comprehensive study and survey of the present laws of the state governing the licensure of professional practice, including the laws relating to optometry, dentistry, pharmacy, nursing, podiatry, osteopathy, and physiotherapy, and to consider the necessity or desirability of extending, adding to, or otherwise revising the present laws of the state to require the licensing of other practices relating to human health and physical or mental well-being. A. 1823 and S. 1557, propose the creation of 50 state scholarships for professional nursing. A. 1908, to amend the public health law, proposes that reports forwarded to the state department of health relating to cancer and other malignant tumors shall be made available on certification by the state department of health to any duly licensed physician practicing in New York state who desires such report for purposes of cancer research. A. 1912 and S. 1834, to amend the law relating to mental hygiene, propose to authorize the commissioner to examine, inspect, and investigate mental hygiene clinics, child guidance clinics, or other facilities treating mental illness, epilepsy and emotional disorders. A. 1913, to amend the law relating to the certification of qualified psychiatrists, proposes that such persons shall have had five years' training and experience approved by the board in the care and treatment of persons suffering from mental disorders. A. 1917, to amend the mental hygiene law relating to the appointment and qualification of a commissioner of mental hygiene, proposes that such commissioner shall be a reputable physician duly licensed to practice medicine in the state of New York, who shall have had at least 10 years' experience in the practice of his profession, confined wholly or substantially to the care and treatment of persons suffering from nervous and mental disorders of which at least five years shall have been as administrative head of a public institution for the care and treatment of persons afflicted with nervous and mental disorders or any position of similar and equivalent administrative responsibility. A. 2014 and S. 1642, propose the creation of a state board of physiotherapy examiners. A. 2015 and S. 1687, propose the enactment of a comprehensive state-wide system of health insurance. A. 2025 and S. 1587, to amend the public health law, propose conditions under which a deceased person may authorize dissection of his body after his death and propose the classes of person who may consent to such a dissection in the event that the deceased has made no direction prior to his death. A. 2027 and S. 1254, propose that in any case in which a state or political subdivision pays all or part of the cost for medical or dental expense indemnity or hospital service the subscriber shall have the right to select for such expense indemnity or service any nonprofit medical care plan authorized by the superintendent of insurance. A. 2103, proposes to make it unlawful for any employer to require any employee or applicant for employment to pay the cost of a medical examination or the cost of furnishing any records required by the employer as a condition of employment. A. 2039 and S. 1291, propose to make municipalities liable for the malpractice of resident physicians and interns under certain circumstances. A. 2186, to amend the mental hygiene law, proposes to authorize the commissioner to set aside a building for the purpose of conducting studies in causes, nature, and treatment of senile psychoses,

to discover and apply more efficient measures of prevention, treatment, and cure of such disorders. A. 2191 and S. 1774, propose an appropriation to the state department of health for the purpose of conducting experiments in cooperation with the medical society of New York state in mass detecting diseases in their early stages through the process of multiphasic screening. A. 2324, proposes the establishment as part of the department of health of a heart institute for the purpose of research and training as to the cause and cure of heart diseases. S. 1072, proposes to make it unlawful for any person to present any television program depicting a physician or nurse endorsing any product or making any report on a product unless such person actually is a licensed physician or nurse. S. 1121, proposes to authorize membership corporations furnishing medical expense indemnity to furnish podiatric care provided through duly licensed podiatrists. S. 1269, proposes to make it unlawful for any person to obtain or attempt to obtain a barbiturate drug or prescription by fraud or forgery. S. 1285, proposes regulations for the temporary licensing of physiotherapists working under the supervision of a duly incorporated hospital or clinic or a political subdivision of the state. S. 1356, to amend the law relating to prorating medical expense indemnity allowances, proposes that nothing shall prohibit a medical expense indemnity corporation from prorating a medical expense indemnity allowance among two or more physicians in proportion to the services rendered by each such physician at the request of the subscriber, provided that prior to payment thereof such physicians shall submit both to the medical expense indemnity corporation and to the subscriber statements itemizing the services rendered by each such physician and the charges therefor. S. 1408, to amend the education law, proposes increased penalties for the illegal practice of medicine. S. 1440, proposes to repeal the law relating to smallpox vaccination reports by physicians. S. 1642, proposes the creation of a state board of physiotherapy examiners. S. 1654, proposes to authorize the use of the injunctive process to restrain violations of the medical practice act. S. 1777, proposes the establishment of an adult hygiene and geriatrics program designed to improve and protect the health and vitality of middle-aged and elderly citizens of the state. S. 1789, to amend the education law, proposes to redefine the practice of medicine as including mental or nervous disorders. S. 1850, proposes an appropriation to the state department of health for the purpose of conducting a pilot experiment in the physical rehabilitation of old persons in old-age homes, nursing homes, or hospitals and a community demonstration project in physical rehabilitation in a small and moderate-sized community.

Bill Enacted.—A. 4, has become Ch. 10 of the Laws of 1954. It is a community mental health services act.

South Carolina

Bills Introduced.—H. 1750, proposes that no superintendent of any institution of learning and no school board or principal of the school board shall admit as a pupil any child or person who cannot produce satisfactory evidence of having been vaccinated for smallpox and inoculated for diphtheria as often as may be directed by ordinance of the city or town in which the school is located. H. 1751, proposes that every doctor, midwife, nurse or other person attending the delivery of a child shall instill or have instilled into the eyes of the baby within one hour after birth, some effective prophylactic approved by the state department of health for the prevention of blindness from ophthalmia neonatorum. S. 504, proposes the creation of a state board of homeopathic medical examiners.

Virginia

Bills Introduced.—H.J.R. 31, proposes to direct the advisory legislative council to make a study and report upon such measures as are necessary for the control and elimination of rabies. H. 56, proposes a licensing law for opticians. H. 146, proposes to require each physician, optometrist, or other person, who upon examination of the eyes of any person determines that such person is blind, to immediately report the name and address of such person to the proper state authority. H. 326, proposes to authorize the maintenance of a hospital farm for the care, treatment, and rehabilitation of inebriates. H. 343, proposes that any physician or other practitioner who makes an examination physical or mental of a person shall, upon the written request of such person, furnish a copy of all reports made of such examination or treatment. S.J.R. 7, proposes a creation of a commission to study the medical scholarship program. S.J.R. 18, proposes the creation of a commission to study the desirability and feasibility of providing specially designed geriatric facilities for the care of aged patients. S. 32, to amend the law relating to the definition of dangerous drugs, proposes to include in such list, among others, amphetamine, the antibiotics penicillin and streptomycin, and drugs that have been found by the State Board of Pharmacy to be dangerous. S. 47, to amend the medical practice act, proposes to exempt therefrom members of the Air Corps in active service. S. 48, to amend the medical practice act, proposes certain changes in the listing of grounds for the revocation of a license by, among other things, adding the use of intoxicating liquors, narcotics, or drugs to the extent that the licensee is unfit for the performance of his professional obligations and duties. S. 100, proposes to require persons desiring to employ as a domestic servant to furnish the employer with a certificate from a physician licensed to practice medicine in the state or from the public health officer for the county or city in which the person resides, certifying that such person is not suffering from any infectious, contagious, communicable, or dangerous disease. S. 181, proposes regulations for the control of rabies. S. 203, proposes regulations for the granting of scholarships to medical students who will agree to engage in the roll of practice of medicine in Virginia after their graduation.

MEDICAL NEWS

CALIFORNIA

Hospitals Built with Hill-Burton Aid.—The Hospital Survey and Construction Program (Hill-Burton), which was passed by the 79th Congress, and which became effective Aug. 13, 1946, established a basis for the allocation of federal funds to assist local communities throughout the nation in building hospitals and health facilities. The state of California by enactment of chapter 327, Statutes of 1947, established the legal basis for California's participation in this national program. A brochure, entitled "Hospitals for California," published in January, 1953 as a progress report on the administration of the program between 1946 and 1952, points out that the Hill-Burton act and the state law passed made it possible for communities to secure financial assistance in constructing general hospitals, tuberculosis hospitals, chronic disease hospitals, mental hospitals, and

When a project is completed, the local community organization that sponsors the project has clear title to the facility and is not subject to federal control or direction nor to any state control or direction except general provisions of the state law which relates to all hospitals in the state. No assistance is available for operation of the institutions aided in the program. Hospitals that are operated for profit are not eligible for consideration in this assistance program.

California law provides that in the administration of this program the State Department of Public Health will act with the advice of the Advisory Hospital Council, members of which are appointed by the governor of the state. This council receives no compensation for its service, and it also represents the geographical, professional, and consumer interests throughout the state.

New California Hospitals and Health Centers. Reading from top and left to right are Mercy Hospital, Redding; Tahoe Forest Hospital, Truckee; Tulare District Hospital, Tulare; Butte County Health Center, Oroville; Merced County Hospital, Merced; and Memorial Hospital, Modesto.

public health centers. The federal funds are allocated to states each year, the states being responsible for the distribution of funds to individual projects. Each state is required to engage in continuous research and investigation of hospital needs within the state. These data are revised each year to reflect the changing conditions and needs of the state, and on this information a state plan is developed which evaluates the relative need for additional hospital facilities in the various areas of the state.

Physicians are invited to send to this department items of news of general interest, for example, those relating to society activities, new hospitals, education and public health. Programs should be received at least three weeks before the date of meeting.

Many communities and public agencies have developed needed hospital facilities since 1946 without financial assistance from federal or state funds. Hill-Burton aid has been used for 77 hospitals and health facility projects throughout the state of California; of these 13 are public health centers and 64 are hospitals. In this period, including hospitals completed, under construction, and in advanced stages of planning, there has been an expansion of 22,600 beds throughout California, of which about 4,113 were created with the assistance of the program. About 9,500 of the 22,600 beds are mental hospital beds, principally in state mental hospitals. Eliminating mental hospitals from consideration, the Hospital Survey and Construction Pro-

gram has assisted about one-third of the hospital expansion that has occurred in California since 1946. During the seven fiscal years (1947-1948 to 1953-1954), \$20,084,863 in federal and \$11,884,212 in state funds have been allocated to projects in this program.

Principal emphasis in the program has been on acute general hospital facilities. About 3,200 of the beds provided with the assistance of the program are general hospital beds. Fifty-three of the 77 projects have been general hospitals. Six allocations have been made to hospitals for patients with chronic diseases, 3 to tuberculosis hospitals, 2 to mental hospitals, and 13 to health centers. Emphasis during the first years of the program was on assistance to projects in the extremely isolated rural areas in which there were no hospital facilities. While allocations of funds to areas of this type are being continued, increasing emphasis in the program is being placed on allocations to the more populated areas, particularly rapidly growing suburbs of large cities. Some of the hospitals and health facilities that have been built under the Hill-Burton program in California are shown in the pictures on the opposite page.

The California Department of Public Health has prepared a supplement to the aforementioned brochure summarizing the state plan for 1953-1954. That revised state plan is based on Bureau of Census estimates of civilian population in California as of July 1, 1951, of 10,648,000 in comparison with 10,421,000, which was used in the 1952-1953 state plan. The 1953-1954 state plan estimates of bed needs for each of the 110 general hospital service areas are based on an analysis of hospital usage in California. The supplement states that the average resident of California spends about one patient day per year in a general hospital, though experience in various parts of the state varies widely. The Department of Public Health and the Advisory Hospital Council both believe that consideration of hospital usage in the establishment of bed-need estimates is a better method than such estimates as ratio of beds per 1,000 population.

CONNECTICUT

Annual Cancer Conference in New Haven.—The annual Connecticut Cancer Conference for Physicians, March 10, 1-5:45 p. m. at the Hotel Taft, New Haven, sponsored by the American Cancer Society, Association of Connecticut Tumor Clinics, Connecticut State Medical Society, and the Connecticut State Department of Health, will open with a new motion picture on lung cancer, which will be followed by "The Relation of Fundamental Research to Cancer Chemotherapy" by Dr. Jack Davidson, New York; "Primary Cancer of the Lymph Nodes" by Dr. George L. Kauer, New York; "Value of the Papanicolaou Technique in the Diagnosis of Cancer" by Dr. N. Chandler Foot, New York; and a question and answer panel. At 3:30 p. m. the Memorial Center staff, New York, will present a panel discussion on management of the patient with advanced cancer. The medical aspects of the subject will be discussed by Dr. Raymond W. Houde, the surgical aspects by Dr. Lemuel Bowden, and the radiation aspects by Dr. James J. Nickson. A question and answer panel and a social hour will conclude the conference.

ILLINOIS

Compulsory Rabies Inoculations.—Following increasing reports of dog bites in the Chicago area, compulsory rabies inoculation for dogs was recently extended to all of Cook County at the request of Dr. John B. Hall, head of the county health department. The quarantine requiring that all dogs be kept leashed, muzzled, or confined, has been in effect in suburban towns for several weeks, and Chicago has been under a rabies quarantine since Dec. 7, with compulsory rabies shots instituted Feb. 4. According to the board of health report, from Jan. 1 through Feb. 7 a total of 1,486 dog bites were reported in Chicago. During the same period, 26 dogs were found to have had rabies, and 103 persons who were exposed to them began receiving antirabies treatment. The January figures showed a marked increase over the preceding months, 948 dog bites having been reported in December and 740 in November. E. C. Khuen, D.V.M., Evanston, has been appointed rabies inspector for Cook County.

Chicago

Cardiac Conference at Cook County.—An open clinicopathological cardiac conference will be held March 12, 11 a. m. to 12 noon, in the Children's Amphitheatre, Cook County Hospital, 700 S. Wood St. Dr. Egbert H. Fell, attending surgeon in cardiology, will present "Experiences in Cardiac Surgery." Discussion will be by Dr. William E. Adams, professor, department of surgery, University of Chicago Clinics.

Personal.—Dr. Noah D. Fabricant, clinical assistant professor of otolaryngology, University of Illinois College of Medicine, will present "Current Progress in Medication of the Ear, Nose, and Throat," at a meeting of the Pima County Medical Society in Tucson, Ariz., March 9.—Dr. Max Thorek recently delivered the 1954 Cushing memorial lecture "Impending Death Under Anesthesia" before the faculty of the medical school of McGill University Faculty of Medicine in Montreal, Canada.

KENTUCKY

Rural Health Conference.—"Help Yourselves to Health" will be the theme of the Kentucky Rural Health Conference that will be held March 10-11 at the Kentucky Hotel, Louisville, under the sponsorship of the Kentucky Rural Health Council, of which Dr. Walter L. O'Nan, Henderson, is chairman. Dr. C. Wyatt Norvell, New Castle, chairman of the rural health committee of the Kentucky State Medical Association, will preside at the opening session Wednesday afternoon. Greetings by Dr. J. Duffy Hancock, Louisville, president, Kentucky State Medical Association, will be followed by the address "Rural Health—You Can Do Something About It" by Dr. E. Bruce Underwood, Louisville, commissioner of health, Kentucky State Department of Health. At 2:15 p. m. there will be a symposium on farm and home safety. Dr. Wendell Hurt, Scottsville, will present "A Young Doctor Looks at a Rural Community," and Dr. Mildred E. Gabbard, Booneville, will have as her topic "A Community Finds Its Health Needs." The session will end with group discussion periods, with Dr. Donald L. Graves, Frenchburg, serving as group chairman for "Finding Your Community's Health Needs." Speakers at the banquet, 6:30 p. m., will be the Hon. Keen Johnson, Richmond, former governor of Kentucky, whose topic will be "Health Is Everybody's Business," and Mr. Clarence Miller, Shelbyville, whose presentation will be "A Farmer Looks at the Kentucky Rural Medical Scholarship Fund." On Thursday morning Aubrey D. Gates, Little Rock, Ark., Field Director, A. M. A. Council on Rural Health, will discuss "What Rural Health Councils Can Do," and reports from Kentucky rural health councils in action will be given under the heading "We Are Helping Ourselves to Health."

MICHIGAN

Lecture by Dr. Ravdin.—Dr. Isidor S. Ravdin, professor of surgery, University of Pennsylvania School of Medicine, Philadelphia, will discuss biliary tract disease in the Henry Ford Hospital auditorium, Detroit, March 9, 8:15 p. m.

Annual Clinical Institute.—Physicians from neighboring states and Ontario are invited to the annual Michigan Clinical Institute at the Sheraton-Cadillac Hotel, Detroit, March 10-12. Dr. Wilfrid Haughey, Battle Creek; will be general chairman. The institute is sponsored by the Michigan State Medical Society, Wayne County Medical Society, Michigan Heart Association, American College of Surgeons, the medical schools of Wayne University and the University of Michigan, and related organizations. The sessions will open at 9 a. m. Wednesday with a discussion of surgical treatment of thyroid disease by Dr. Bentley P. Colcock, Boston. At 11 a. m. Dr. Eugene P. Pendergrass, Philadelphia, will deliver the R. S. Sykes lecture "Difficulties in Early Diagnosis of Lung Cancer," followed at 11:30 a. m. by Dr. John H. Warvel, Indianapolis, whose topic will be "Treatment of Diabetic Emergencies." The Michigan Foundation of Medical and Health Education lecture, "Vaccination for Poliomyelitis," will be delivered Thursday, 11:20 a. m., by Dr. Albert B. Sabin, Cincinnati. At 4:40 p. m. a presentation "Alcoholism and Cardiovascular Disease" by Dr. Frederick W. Niehaus, Omaha, will precede the daily 5 o'clock discussion conference.

The Friday morning session will begin at 9:20 a. m. with a discussion of congenital cardiac malformations by Dr. Stanley Gibson, Chicago, and end at 11:35 a. m. with the presentation "Pathogenesis and Treatment of Essential Hypertension" by Dr. George E. Wakerlin, Chicago. At 4:10 p. m. Dr. Stanley F. Hampton, St. Louis, will have as his topic "Differential Diagnosis and Treatment of Extrinsic and Intrinsic Asthma," and at 4:40 p. m. Dr. Reginald G. Bickford, Rochester, Minn., will present "Sensory Precipitation of Seizures."

MISSOURI

Consultants and Lecturers.—The St. Louis University School of Medicine is presenting four programs by guests, who will offer consultation in their fields and deliver lectures. Dr. Leland D. Stoddard, associate professor of pathology, University of Kansas School of Medicine, Kansas City, Kan., was scheduled to present the following series March 4-6: Thursday, "Development and Destiny of Carcinoma-in-Situ"; Friday, "Chronic Myeloses"; and Saturday, a seminar, "Research Into Acute Tubular Necrosis." The lectures, sponsored by the department of pathology, will be open to faculty members in the clinical and basic science departments, students, and others interested. March 18-20 Dr. John Harman, associate professor of pathology, University of Wisconsin Medical School, Madison, will visit the department. On Thursday his topic will be "Metabolism of Skeletal Muscle," and Friday he will lecture sophomore medical students on enzymatic processes in cloudy swelling. The seminar on Saturday will be on "Instrumentation in Medical Research."

NEBRASKA

Lincoln-Lancaster Conference.—The Lancaster County Medical Society invites physicians to attend its second Lincoln-Lancaster Medical Conference, March 11, at the Cornhusker Hotel in Lincoln. The following will participate in the program: Dr. Paul H. Lorhan, professor of anesthesiology, Dr. Leroy A. Calkins, professor of obstetrics and gynecology, and Dr. Max S. Allen, University of Kansas School of Medicine, Kansas City, Kan., Dr. Walter L. Palmer, professor of medicine, University of Illinois, Chicago, Dr. Robert D. Moreton, Fort Worth, Texas, Dr. Robert Elman, clinical professor of surgery, Washington University School of Medicine, St. Louis, and Dr. Howard A. Rusk, chairman, department of physical medicine and rehabilitation, New York University College of Medicine.

NEW YORK

Symposium on Air Pollution.—The second annual symposium on air pollution and its control will be held at Wagner Memorial Lutheran College, Staten Island, March 6, from 9:30 a. m. to 4:30 p. m., under the auspices of the department of bacteriology and public health of the college.

Dr. Meigs to Speak on Cancer.—The Central New York Association of Gynecologists and Obstetricians will have as guest on March 9 Dr. Joe Vincent Meigs, clinical professor of gynecology, Harvard Medical School, Boston, who will direct a seminar, 2-4 p. m. at Syracuse Memorial Hospital. Dinner, 6:30 p. m., at the University Club will precede the George B. Broad lecture at the college of medicine auditorium, 8:30 p. m., at which Dr. Meigs will present "Carcinoma of the Cervix—35 Years' Experience."

Chronic Disease Week.—Chronic Disease Week of the Jewish Sanitarium and Hospital for Chronic Diseases, Brooklyn, (March 8-12) will be devoted to a postgraduate course on chronic diseases of the musculoskeletal system. Daily teaching clinics, presentations, and panel discussions will give emphasis to advances in clinical and laboratory diagnosis, therapy, and rehabilitation. On Monday, 8:30 p. m. in the auditorium of the Freeman Pavilion, Rutland Road and East 49th St., Brooklyn, Dr. Benjamin Kramer, professor of clinical pediatrics, State University of New York College of Medicine at New York City, Brooklyn, will present "Problems of Bone Formation and Resorption," and Dr. Edward C. Reifenshtein Jr., director of the division of biological and therapeutic research, Schering Corporation, will discuss "Bones and Hormones."

New York City

Cancer Lecture.—Dr. Abraham Cantarow, professor of biochemistry, Jefferson Medical College of Philadelphia, will present the sixth Isidore W. Held lecture, "Certain Host-Tumor Interrelations in Experimental Cancer," March 8, 8:30 p. m., in the Beth Israel Hospital Auditorium, Stuyvesant Square East and 17th Street.

Meeting on Gastroenterology.—The New York chapter of the American College of Gastroenterology will present the following program at the New York Academy of Medicine, 2 E. 103rd St., March 8 at 8:30 p. m.:

Hormonal Influences in Peptic Ulcer Disease, Seymour J. Gray, Boston.
Evaluation of the Combined Manometric and Cholangiographic Studies in Europe, Roy Upham, New York.
Therapeutic Aspects in Liver Cirrhosis, Isidore Snapper, Brooklyn.

Roentgenograms of gastrointestinal cases will be shown for diagnosis and discussion at 8 p. m.

Cardiovascular Problems in Diabetes Mellitus.—At the combined meeting of the New York Heart Association, Inc. and the Clinical Society of the New York Diabetes Association, March 9, 8:30 p. m., in Hosack Hall, New York Academy of Medicine Building, 2 E. 103rd St., New York 29, cardiovascular problems in diabetes mellitus will be discussed. Dr. Irving P. Graef will preside over the following program:

Relation of Control of Diabetes Mellitus to Plasma Protein Patterns and the Development of Vascular Degeneration, E. Perry McCullagh, Cleveland.
Kimmelstiel-Wilson Syndrome and Its Clinical Variants, Harold Rifkin, New York.
Medical Management of Peripheral Arterial Occlusive Disease, Karl Harpuder, New York.
Arterial Resection and Endarterectomy in Arterial Occlusive Disease, Henry T. Bahnson, Baltimore.

OREGON

Dr. Stewart to Address Surgical Society.—Members of the medical profession are invited by the Portland Surgical Society to a meeting March 12-13 in the library, University of Oregon Medical School, Portland. Dr. John D. Stewart, professor of surgery, University of Buffalo School of Medicine, will discuss "Traumatic Shock" at 11 a. m. and after luncheon at the University Club will serve as moderator for a panel on lesions of the large bowel. Discussants will include Drs. Louis P. Gambee, Dean B. Seabrook, and Karl H. Martzloff, Portland. After dinner at the Multnomah Hotel, Dr. Stewart will speak on massive gastrointestinal bleeding. At 10 a. m. Saturday, he will be moderator for a panel and at 11 o'clock will present "Thoraco-abdominal Approach for Upper Abdominal Surgery."

PENNSYLVANIA

Society News.—On March 16 the Allegheny County Medical Society, 225 Jenkins Building, Pittsburgh, will hold a joint meeting with the Diabetes Association. Dr. Garfield G. Duncan, Philadelphia, will speak on disordered carbohydrate metabolism.

Tour to San Francisco with Stopovers.—The Medical Society of the State of Pennsylvania is arranging a tour (limited to 150 persons) to San Francisco and return for the A. M. A. annual meeting in San Francisco, June 21-25. The itinerary includes stops at Colorado Springs, Colo., Lamy, N. Mex., Grand Canyon, Ariz., and Riverside, San Diego, and Los Angeles in California, in all of which places sight-seeing tours have been arranged. Tours have also been planned for the following stops on the return journey: Portland, Ore., Seattle, Glacier National Park in Montana, and Waterton Lakes Park in Canada.

Philadelphia

Pediatrics Lecture.—Beta chapter, Phi Lambda Kappa, at Jefferson Medical College of Philadelphia, will present Dr. Robert E. Gross, William E. Ladd professor of children's surgery at Harvard Medical College, Boston, March 9, 8:30 p. m., at McClellan Hall, 1025 Walnut St. Dr. Gross, who is surgeon in chief at the Children's Hospital in Boston, will discuss some surgical problems of infancy.

Woman's College Founders' Day Forum.—In honor of Founders' Day, March 11, the Woman's Medical College of Pennsylvania will present a Health Assurance Forum, 4-10 p. m., in the auditorium of the college at Henry Ave. and Abbottsford Road. The forum will be preceded by dedication of the Martha Tracy Memorial for Preventive Medicine. After the address of welcome by Dr. Burgess L. Gordon, president of the college, Dr. Ellen C. Potter, Philadelphia, will read "The History of Preventive Medicine at the Woman's Medical College." "The Positive Approach to Health Maintenance" by Dr. James P. Dixon, Philadelphia commissioner of health, will precede a visit to the memorial. Dr. Anthony J. Lanza, New York, will serve as moderator for a panel on preventive medicine and industry, 4:10-5:10 p. m., in which the participants will be Anna M. Baetjer, Sc. D., Baltimore, Dr. Francis J. Braceland, Hartford, Conn., and Dr. William A. Sawyer, Rochester, N. Y. Dr. Donald A. Covalt, New York, will be moderator for the panel "Going Back to Work," 5:15-6:15 p. m., with Drs. Ronald F. Buchan, Newark, and Earl C. Bonnett, New York, and Miss Mary E. Switzer, Washington, D. C., as collaborators. The after-supper program at 8 p. m. will include a presentation on optimal health for the Delaware Valley by Mr. David E. Williams, Philadelphia. The final panel, "Health Maintenance for Enhancing Labor-Management Accord," 8:15-9:15 p. m., will be moderated by Dr. Edward C. Holmblad, Chicago, and presented by Drs. Leo Price, New York, and Norbert J. Roberts, Philadelphia, and Mr. Bayard L. England, Atlantic City. "To Keep Our Bodies as Fit as Our Machines" will be the final presentation, 9:15 p. m., by Dr. George M. Piersol, Philadelphia.

Pittsburgh

Educational Television Station.—WQED, a nonprofit enterprise administered by a board of directors representing education, civic, and community interests, is scheduled to start broadcasting in March over channel 13 as one of the pioneer educational television stations. The physical facilities of the station are located in Oakland, Pa., in a building donated by the University of Pittsburgh. The Westinghouse KDKA tower above the stadium will be used as the transmitting point, and the money for equipment has been donated by the Arbuckle-Jameson Foundation, the Ford Foundation, and the A. W. Mellon Trust. It is expected that the station will cover a 10 county area surrounding Pittsburgh. A committee of the Allegheny County Medical Society has met with the station management as a preliminary to developing telecasts on health and medical subjects (see THE JOURNAL, Dec. 19, 1953, p. 1459).

TENNESSEE

Postgraduate Courses.—The University of Tennessee College of Medicine, Memphis, in cooperation with the John Gaston Hospital and Le Bonheur Children's Hospital, will offer the following postgraduate courses for midsouth physicians during 1954: pediatrics, March 10-12; abdominal surgery, March 21, April 1-2; obstetrics and gynecology, May 19-21; trauma, July 28-30; management of simple fractures, Sept. 15-17; and clinical electrocardiography, Oct. 6-8. Further information may be obtained from the Postgraduate Department, 4 S. Dunlap, Memphis.

TEXAS

Telephone Broadcast from Austin.—Dr. Henry M. Winans, Dallas, will be moderator for a telephone broadcast, March 9, which, under the sponsorship of the Council on Medical Education and Hospitals of the Texas Medical Association, will originate in the headquarters of the Texas Medical Association in Austin. Dallas physicians will present a program on diet, Dr. Donald W. Seldin speaking on diet in cardiovascular disease, Dr. Edwin L. Rippey on diet in metabolic disease, and Dr. Tate Miller on diet in gastrointestinal disease.

Annual Tumor Conference.—The third annual state tumor conference, sponsored by the Wichita County Medical Society Tumor Clinic, the American Cancer Society, and the state department of health, will be held March 13 at Midwestern University in Wichita Falls. This clinic, which is approved for

credit in formal postgraduate training, is open to physicians without a registration fee. After the address of welcome by Dr. James T. Lee, Wichita Falls, president of the Wichita County Medical Society, the following program will be presented:

- Shields Warren, Boston, (1) Diagnosis and Treatment of Cancer of the Thyroid and (2) Radioisotopes in Treatment of Tumors.
- Alton Ochsner, New Orleans, (1) Early Diagnosis and Treatment of Cancer of Stomach and (2) Early Diagnosis of Cancer of Lung.
- Jesshill Love, Louisville, Ky., (1) Cancer in General Practice and (2) Treatment of Malignant Disease.

Dr. Bailey R. Collins, Wichita Falls, director of the clinic, will preside over the morning session and Dr. David H. Allen, Wichita Falls, over the afternoon session, which will end with a question and answer period.

GENERAL

Southeastern Surgical Congress.—The Southeastern Surgical Congress will hold its annual session at the Dinkler-Tutwiler Hotel, Birmingham, Ala., March 8-11. Dr. James R. Young, Anderson, S. C., will deliver the presidential address, "The Value of a Cancer Clinic in a Community Hospital." Numerous guest presentations will be made. Each afternoon session will end with a panel discussion at 4:30 p. m. (Monday, traumatic lesions; Tuesday, esophagogastric intestinal hemorrhage; Wednesday, liver and gallbladder pathology; and Thursday, surgical management of peptic ulcer). The banquet is scheduled for Wednesday, 7:30 p. m.

Eastern Conference of Radiologists.—The section on radiology of the Medical Society of the District of Columbia will be host to the Eastern Conference of Radiologists at its session, March 12-13, Statler Hotel, Washington, D. C. The constituent organizations of the conference are the New England, the New York, and the Philadelphia roentgen ray societies, and the radiological sections of the Medical Society of Baltimore and of the District of Columbia medical society. The program will include a visit to the National Institutes of Health. Information may be obtained from Dr. Karl C. Corley, Chairman, Committee on Arrangements, 1835 Eye St., N. W., Washington 6, D. C.

Medical Art on Tour.—Smith, Kline & French Laboratories, Philadelphia, have arranged a tour of a medical art exhibit containing the works of Rembrandt, Goya, Daumier, Vesalius, Toulouse-Lautrec, and other masters, to be shown at medical colleges and hospitals across the country. The collection, entitled "Ars Medica," composed of 85 prints depicting the practice of medicine over the centuries, was assembled by the Philadelphia Museum of Art. It has gone on display at the University of Texas Medical Branch, Galveston, Baylor University College of Medicine, Houston, and the Southwestern Medical School in Dallas. During March the exhibit may be seen as follows:

- March 15-19, University of Oklahoma School of Medicine, Oklahoma City.
- March 22-28, University of South Dakota School of Medicine, Vermillion.
- March 30-April 5, University of Nebraska College of Medicine, Omaha.

Meeting on Prevention of Blindness.—The National Society for the Prevention of Blindness will hold its annual conference at the Jefferson Hotel, St. Louis, March 10-12. Wednesday morning will be devoted to discussion on health for preschool and school age children with impaired eyesight and on interprofessional relationships in eye care. The Wednesday afternoon workshop, "Meeting the Needs of Partially Seeing Children in Rural Areas," will be continued Thursday morning. Thursday afternoon consideration of medical aspects of prevention of blindness will include presentations on strabismus, current status of trachoma, reading disabilities, measurement of aqueous outflow, and current concepts about cataracts. The Friday morning session will be concerned with progress in industrial vision conservation. The society is supported entirely by voluntary contributions from more than 48,000 members and contributors in every state.

American Orthopsychiatric Association.—For its annual meeting at the Hotel Commodore, New York, March 11-13, the American Orthopsychiatric Association has scheduled 90 papers, 18 case workshops, and 1½ days of mental health film show-

ings. The presidential session, Thursday, will be concerned with causes of family breakdown, and Dr. Hyman S. Lippman, St. Paul, will open this program. Symposia will be presented, including "Qualifications for Psychotherapists"; "Use of Spontaneous Art in Psychotherapy"; "Techniques, Methodologies and Problems in Community Mental Health Research"; "The Hospitalized Child"; "A New Pattern for Mental Health Services in a Children's Court"; and "Child Development Center Projects." Workshops will include a case report on a schizophrenic boy, gastrointestinal disturbances in the very young child, psychological problems of the congenitally blind child, dynamics of obesity, and treatment of the adolescent delinquent.

Meeting on Electroencephalography.—The Western Society of Electroencephalography will hold its annual meeting March 7-8 at Del Monte Lodge, Pebble Beach, Calif. The sessions will open at 2 p. m. Sunday with presentation of "Headache and the EEG" by Commander Henry S. Colony, M. C., U. S. N., and Lieut. W. F. Stafford, M. C., U. S. N. R., and will close at 3 p. m. Monday with electrographic observations on gargoylism in siblings by Drs. Paul A. Shea and Ward W. Woods, San Diego, Calif. At 10 a. m. Monday morning Dr. Charles L. Yeager, San Francisco, will present "Methods of Quantifying Electroencephalographic Data"; at 2:30 p. m. Sunday Dr. Yeager and Dr. Edward E. Shev, San Francisco, will give "An Analysis of Electroencephalographs in Post-Traumatic, Closed, Chronic Head Injuries"; and at 3 p. m. Dr. Yeager and Dr. Frances Phillips Sheridan, Imola, Calif., will give a preliminary report on EEG as a prognostic and diagnostic aid in the study of the senescent individual. Other presentations will include "Observations on Relationship Between Psychomotor Epilepsy, Sexual Psychopathy, and Pathological Intoxication" by Dr. George N. Thompson, Los Angeles, "The Electroencephalogram in Hyperactive Behavior Disorders" by Dr. Leon Oettinger Jr., San Marino, Calif., and "Status Petit Mal" by Dr. Leslie B. Mann, Los Angeles. Dr. Walter J. Friedlander, Veterans Administration Hospital, San Francisco, will present an analysis of 1,013 consecutive EEG's correlated with their clinical findings.

FOREIGN

Association for Rehabilitation of the Severely Injured.—A registered association for rehabilitation of the severely injured has been founded in Berlin, Germany, with the participation of numerous organizations interested in health and social service, the association of the war injured, public and private welfare organizations, and the executive committees of employer and employee organizations. An exhibit is being prepared by the newly founded association for presentation in the spring of 1955 in Berlin. Experts interested in rehabilitation problems will be invited to a planning meeting early this summer in Berlin. The Federal Ministry of Work has appropriated 10,000 Deutsche marks (about \$2,400) and the Senate of Berlin, 50,000 Deutsche marks (about \$12,000) for promotion of this plan. Suggestions should be addressed to the business office of the association, Berlin-Wilmersdorf, Sachsische Strasse 28.

MEETINGS

AMERICAN MEDICAL ASSOCIATION: Dr. George F. Lull, 535 North Dearborn St., Chicago 10, Secretary.
1954 Annual Meeting, San Francisco, June 21-25.
1954 Clinical Meeting, Miami, Florida, Nov. 30-Dec. 3.
1955 Annual Meeting, Atlantic City, N. J., June 6-10.
1955 Clinical Meeting, Boston, Nov. 29-Dec. 2.
1956 Annual Meeting, Chicago, June 11-15.

AERO MEDICAL ASSOCIATION, Hotel Statler, Washington, D. C., March 29-31. Dr. Thomas H. Sutherland, P. O. Box 26, Marion, Ohio, Secretary.

ALABAMA, MEDICAL ASSOCIATION OF THE STATE OF, Mobile, April 15-17. Dr. Douglas L. Cannon, 537 Dexter Ave., Montgomery, Secretary.

AMERICAN ACADEMY OF GENERAL PRACTICE, Cleveland, March 22-25. Mr. Mac F. Cahal, 406 West 34th St., Kansas City 2, Mo., Executive Secretary.

AMERICAN ACADEMY OF NEUROLOGY, Shoreham Hotel, Washington, D. C., April 29-May 1. Dr. Alexander T. Ross, 1040 West Michigan St., Indianapolis 7, Secretary.

AMERICAN ASSOCIATION OF ANATOMISTS, Hotel Galvez, Galveston, Texas, April 7-9. Dr. Normand L. Hoerr, 2109 Adelbert Road, Cleveland 6, Secretary.

AMERICAN ASSOCIATION OF IMMUNOLOGISTS, Ambassador Hotel, Atlantic City, N. J., April 11-15. Dr. John Y. Sugg, 1300 York Ave., New York, Secretary.

AMERICAN ASSOCIATION OF PATHOLOGISTS AND BACTERIOLOGISTS, Philadelphia, Pa., April 8-10. Dr. Alan R. Moritz, 2085 Adelbert Road, Cleveland 6, Secretary.

SOUTH DAKOTA: Examination. June 11-12. Sec., Dr. Gregg M. Evans, 310 E. 15th St., Yankton.

TENNESSEE: Examination. Memphis, March 17-18. Sec., Dr. O. W. Hyman, 874 Union Ave., Memphis 3.

TEXAS: Examination. April 1954. Location determined by number of applicants from different sections of the state. Sec., Brother Raphael Wilson, C.S.C., 407 Perry-Brooke Bldg., Austin.

WISCONSIN: Examination. Madison, April 3 and June 5. Final date for filing application is March 26 and May 28. Sec., Dr. W. H. Barber, 621 Ransom St., Ripon.

*Basic Science Certificate required.

DEATHS

Hoyt, Robert Eustis * Capt., U. S. N., retired, Washington, D. C.; born in Portsmouth, N. H., Nov. 26, 1879; Harvard Medical School, Boston, 1901; fellow of the American College of Surgeons; in 1902 appointed an assistant surgeon with the relative rank of lieutenant (j. g.) in the Medical Corps, U. S. N.; promoted to captain, Medical Corps, U. S. N., in December, 1921; during his more than 44 years of naval service, commanded the Naval hospitals, Canacao, P. I., Portsmouth, N. H., Washington, D. C., Bethesda, Md., and Annapolis, Md.; commanded the Naval Medical Supply Depot, Mare Island, Calif., and the Naval Dispensary, Navy Department, Washington, D. C.; district medical officer of the 12th naval district, San Francisco, and the 14th naval district, Pearl Harbor, T. H., during the years 1934-1937; served on the U. S. ships Wabash, Texas, Newark, Chattanooga, Buffalo, Franklin, Michigan, Massachusetts, Idaho, Wisconsin, Minnesota, and the hospital ship, USS Mercy, as well as ashore at many Naval medical facilities; in 1946 awarded a letter of commendation, with ribbon, by the Secretary of the Navy for services in command of three naval hospitals from Dec. 7, 1941, until Sept. 2, 1945; placed on the retired list Jan. 1, 1943, and immediately recalled to active duty; released to inactive duty on Feb. 2, 1947; died in the Naval Hospital, National Naval Medical Center, Bethesda, Md., Dec. 19, aged 74.

Minnick, William Tell * Commander, M. C., U. S. N., retired, Philadelphia; born at Wabash, Ind., Aug. 7, 1879; Medical College of Indiana, Indianapolis, 1904; entered the Navy as a chief pharmacist's mate in 1908, and served in that capacity until appointed a lieutenant in the Medical Corps, Aug. 3, 1920; promoted to lieutenant commander, in 1931, and retired from active duty in December, 1931; recalled to active duty in 1939; promoted to commander in 1942 and released from active duty in 1945; veteran of the Second Nicaraguan Campaign and World Wars I and II; awarded the Navy Cross for having distinguished himself by extraordinary heroism and excellent judgment in the performance of duty as a medical officer attached to a small Marine expedition in an engagement near Quilali, Nicaragua, on Dec. 30, 1927; during more than 29 years of active naval service, served on the U. S. ships Galveston, Tennessee, Culgoa, Denver, Powhatan, and Kittery, at the Naval Medical School, Washington, D. C., and at other naval medical activities throughout the world; died Jan. 11, aged 74, of a heart attack.

Alcock, Nathaniel Graham * Iowa City, Iowa; born in Platteville, Wis., Jan. 18, 1881; Northwestern University Medical School, Chicago, 1912; professor emeritus of urology at the State University of Iowa College of Medicine, where he was on the faculty for 34 years; secretary of the Section on Urology of the American Medical Association from 1929 to 1932, when he became chairman; past president of the Iowa State Medical Society; charter member and past president of the Mississippi Valley Medical Society, which in 1949 presented him with its Distinguished Service Award; past president of the North Central Section of the American Urological Association; member of the American Association of Genito-Urinary Surgeons, American Urological Association, and the Clinical Society of Genito-Urinary Surgeons; chief urologist, Mercy Hospital, where he died Dec. 10, aged 72, of hypertensive cardiovascular disease.

Mulky, Carl * Albuquerque, N. Mex.; born in Knoxville, Iowa, in 1877; Chicago Homeopathic Medical College, 1899; Rush Medical College, Chicago, 1900; member of the council and past president of the New Mexico Medical Society; past president of the Bernalillo County Medical Society, New Mexico Trudeau Society, and the New Mexico Tuberculosis Association; member of the American Trudeau Society; fellow of the American College of Physicians; served during World War I;

formerly consultant in tuberculosis to the U. S. Indian Service; past president of the medical staff of the U. S. Indian hospitals, United Pueblos area; president of the medical staff and one of the founders of the State Tuberculosis Sanatorium in Socorro; on the staff of Southwestern Presbyterian Sanatorium; associate staff member, St. Joseph Sanatorium; died Jan. 14, aged 76, of chronic myocarditis.

Saunders, John Turner, Asheville, N. C.; born in St. Elmo, Tenn., July 26, 1898; Columbia University College of Physicians and Surgeons, New York, 1926; clinical instructor in orthopedic surgery at his alma mater from 1931 to 1934; certified by the National Board of Medical Examiners; specialist certified by the American Board of Orthopaedic Surgery; member of the American Academy of Orthopaedic Surgeons; fellow of the American College of Surgeons; served during World War I; affiliated with Memorial Mission, Aston Park, St. Joseph's, and Biltmore hospitals; consultant orthopedic surgeon at the Western North Carolina Sanatorium at Black Mountain; senior consultant orthopedic surgeon for the Veterans Administration Hospital at Oteen and the Asheville Orthopedic Hospital; died Dec. 23, aged 55, of diabetes mellitus and arteriosclerosis.

Gerard, Margaret Wilson * Chicago; born in Chicago Dec. 16, 1894; Rush Medical College, Chicago, 1925; fellow of the Institute of Medicine; member of the American Psychoanalytic Association, American Psychosomatic Society, and the American Orthopsychiatric Association; instructor in anatomy at Northwestern University Medical School from 1918 to 1922; formerly head of the psychiatric service in the University of Chicago's Student Health Service, and later assistant clinical professor of psychiatry and associate professor at division of biological sciences, University of Chicago; at one time psychiatrist at the Institute for Juvenile Research; since 1938 on the staff of the Illinois Children's Home and Aid Society; on the staff of the Institute for Psychoanalysis; died in the Passavant Memorial Hospital Jan. 12, aged 59, of rheumatic heart disease.

West, James Hubert * Tucson, Ariz.; born in Tiffin, Ohio, Dec. 14, 1887; Western Reserve University School of Medicine, Cleveland, 1915; specialist certified by the American Board of Radiology; member of the Cleveland Academy of Medicine and the Radiological Society of North America; life fellow of the American College of Radiology; charter member of the Cleveland Radiological Society; in 1916 commissioned first lieutenant and served with an Ohio National Guard Unit at Fort Bliss; in July, 1917, discharged for physical disability; until his retirement last July was affiliated with the Tucson Medical Center, Pima County General Hospital, and St. Mary's Hospital and Sanatorium, where he died Jan. 8, aged 66, of arteriosclerotic heart disease.

Evans, Everett Idris * Richmond, Va.; born in Norfolk, Neb., April 15, 1907; University of Chicago, The School of Medicine, 1937; professor of surgery and director of the surgical laboratory at the Medical College of Virginia; held a long-time research contract with the army on radiation burns and injuries, particularly in connection with atomic warfare; in 1948 was awarded certificate of appreciation by the army and navy for his research on surgical shock during World War II; member of the American Surgical Association and Southern Surgical Association; fellow of the American College of Surgeons; attending surgeon, Medical College of Virginia, Hospital Division, and Stuart Circle Hospital; died in Washington, D. C., Jan. 13, aged 46, of coronary occlusion.

Lanting, Roelof * East Lansing, Mich.; University of Michigan Medical School, Ann Arbor, 1929; specialist certified by the American Board of Preventive Medicine and Public Health; director of the Shiawassee County Health Department; formerly director of the Delta County Health Department, director of health district 7, comprising Clare, Gladwin, and

* Indicates Member of the American Medical Association.

Arenac counties, and director of the Lansing-Ingham county health unit; served in the European theater during World War II; lieutenant colonel in the air force reserve, attached to 439th Fighter Bomber Wing; affiliated with Owosso (Mich.) Memorial Hospital and Edward W. Sparrow Hospital in Lansing; died Dec. 13, aged 50, of injuries received in an airplane crash.

Ancerawicz, Albert Joseph, Kulpmont, Pa.; Temple University School of Medicine, Philadelphia, 1919; for six years county coroner; served during World War I; died in Danville (Pa.) State Hospital Dec. 24, aged 59, of cirrhosis of the liver.

Astley, George Mason, Philadelphia; University of Pennsylvania Department of Medicine, Philadelphia, 1903; emeritus professor of surgery at Temple University School of Medicine; served during World War I; for many years on the staff of Woman's Hospital; affiliated with Temple University Hospital, where he died Jan. 15, aged 71, of myocardial infarction.

Bernstein, Eugene A., Boston; Harvard Medical School, Boston, 1952; certified by the National Board of Medical Examiners; resident at the Beth Israel Hospital, where he died Jan. 7, aged 34, of acute myelogenous leukemia.

Boland, Benedict Fenwick, Boston; Tufts College Medical School, Boston, 1920; professor of clinical gynecology at his alma mater; member of the New England Obstetrical and Gynecological Society; fellow of the American College of Surgeons; affiliated with Massachusetts General Hospital, Boston City Hospital, and St. Elizabeth's Hospital, where he died Dec. 24, aged 60, of hepatic and renal failure.

Brin, Alfred Ross, Monroe, La.; University of Texas School of Medicine, Galveston, 1938; specialist certified by the American Board of Urology; fellow of the American College of Surgeons; served during World War II and in 1945 received the certificate of merit; on the staffs of St. Francis Sanitarium and the E. A. Conway Hospital; died Jan. 18, aged 38, of acute leukemia.

Broomall, Harold Shoemaker, Philadelphia; University of Pennsylvania School of Medicine, Philadelphia, 1914; died Oct. 31, aged 65.

Bruno, Alexander, New York City; Columbia University College of Physicians and Surgeons, New York, 1913; fellow of the American College of Surgeons; member of the American Trudeau Society; during World War I served as a surgeon with the Red Cross with the rank of captain in France and received the award of the Cross of the Legion of Honor from the French government; died recently, aged 64.

Cohen, Benjamin, Chicago; Chicago Medical School, 1931; affiliated with the Chicago State Hospital; died Jan. 30, aged 53.

Cooper, Clifford, Titusville, Pa.; Western Pennsylvania Medical College, Pittsburgh, 1905; past president of the Crawford County Medical Society; served on the board of health of Titusville; resigned in January 1953 after many years as director of the Second National Bank; member and past president of the Titusville Hospital, where he died Dec. 5, aged 71, of retroperitoneal abscess.

Cuthbert, Fred Sheets, Kokomo, Ind.; College of Physicians and Surgeons of Chicago, School of Medicine of the University of Illinois, 1905; died Nov. 20, aged 77, of coronary thrombosis.

Daniel, John William, Savannah, Ga.; University of Georgia Medical Department, Augusta, 1896; served during World War I; past president of the Georgia Medical Society; formerly member of the state board of health; died Jan. 1, aged 85, of cardiovascular renal disease.

Davis, Deane Darling, Grove City, Ohio; Starling Medical College, Columbus, 1901; veteran of the Spanish-American War; died Jan. 8, aged 75, of acute coronary occlusion.

Ellis, Walter Winthrop, Delaware City, Del.; Jefferson Medical College of Philadelphia, 1905; past president of the New Castle County Medical Society; on the staff of the Delaware Hospital; vice-president of the Delaware City National Bank; died Nov. 27, aged 75, of coronary thrombosis.

Evans, Andrew Jackson, Mineral Wells, Texas; University of Louisville (Ky.) Medical Department, 1909; also a graduate in pharmacy; on the staff of Nazareth Hospital; died Dec. 10, aged 73.

Fort, James Arthur, North, S. C.; Atlanta School of Medicine, 1907; died Nov. 15, aged 73.

Fulton, Harry Lester, Fresno, Calif.; University and Bellevue Hospital Medical College, New York, 1932; member of the Medical Society of the State of New York; served during World War II; affiliated with Veterans Administration Hospital; accidentally shot and killed himself, Jan. 9, aged 46.

Garrett, Clarence Coleman, Fort Worth, Texas; University of Pennsylvania School of Medicine, Philadelphia, 1927; editor of *Bulletin of the Tarrant County Medical Society*; died in All Saint's Hospital Jan. 1, aged 51, of essential hypertension.

Gittlow, Samuel, New York City; Columbia University College of Physicians and Surgeons, New York, 1912; an Associate Fellow of the American Medical Association; fellow of the American College of Physicians; past president of the Bronx County Medical Society, North Bronx Medical Society, and Bronx Pathological Society; consulting physician, Lebanon Hospital and Home and Hospital of the Daughters of Jacob; died in Miami Beach, Fla., Jan. 6, aged 64, of coronary occlusion.

Grudberg, Simon Charles, Kew Gardens, N. Y.; Columbia University College of Physicians and Surgeons, New York, 1907; died in the Bellevue Hospital in New York City, Jan. 2, aged 69.

Hanavan, Eugene Joseph, Buffalo; University of Buffalo School of Medicine, 1915; affiliated with Our Lady of Victory Hospital in Lackawanna, N. Y.; on the staff of the Mercy Hospital, where he died Dec. 20, aged 64, of peritonitis and intestinal obstruction.

Harper, William Frantz, Selma, Ala.; Harvard Medical School, Boston, 1922; member of the Southeastern Surgical Congress; fellow of the American College of Surgeons; on the staff of the Selma Baptist Hospital; died Jan. 1, aged 57, of a heart attack.

Harwell, Carl Mallory, Osceola, Ark.; Memphis (Tenn.) Hospital Medical College, 1909; on the staff of the Osceola Memorial Hospital; died in Roanoke, Va., Dec. 26, aged 73, of coronary thrombosis.

Howard, John Richard, Lake Waccamaw, N. C.; Medical College of Virginia, Richmond, 1924; died in James Walker Memorial Hospital in Wilmington Dec. 24, aged 55, of arteriosclerotic heart disease.

Hunt, William West, East Providence, R. I.; College of Physicians and Surgeons, medical department of Columbia College, New York, 1890; at one time police surgeon; served on the staffs of the Memorial Hospital in Pawtucket and the Rhode Island Hospital in Providence; died Dec. 18, aged 85, of cerebral thrombosis and arteriosclerosis.

Huntington, Ella Edwina, San Diego, Calif.; Pulte Medical College, Homeopathic, Cincinnati, 1900; died Dec. 20, aged 91, of carcinoma of the bladder.

Hurford, Phelps Grant, St. Louis; Washington University School of Medicine, St. Louis, 1908; served during World War I; died Dec. 13, aged 77, of heart disease.

Kandel, Harry Milton, Savannah, Ga.; University of Georgia Medical Department, Augusta, 1926; fellow of the American College of Physicians; served in World War II; formerly vice-president of the Georgia Medical Society; on the staff of St. Joseph's Hospital; died Jan. 4, aged 55, of cerebral hemorrhage.

Kleeberg, Felix, Levittown, N. Y.; Jefferson Medical College of Philadelphia, 1899; died Jan. 3, aged 85, of heart failure.

Lincoln, Robert Edward, Medford, Mass.; Boston University School of Medicine, 1926; served during World War II; died in the Ring Sanatorium in Arlington Jan. 30, aged 54, of acute myocardial infarction.

GOVERNMENT SERVICES

ARMY

Mrs. Wilder Retires.—Mrs. Helenor Campbell Wilder, chief of the section of ophthalmic pathology at the Armed Forces Institute of Pathology, Washington, D. C., recently retired after 30 years of service that brought her to the top in ophthalmic pathology. In 1953 she was honored as "Woman of the Year" for science by the Women's National Press Club, and she will soon receive the Exceptional Meritorious Award, the highest civilian award in the Department of Defense. Brig. Gen. Elbert DeCoursey, director of the Armed Forces Institute of Pathology, stated that her work has advanced the study of the eyes more than 50 years. The disease of the eye that was demonstrated by Mrs. Wilder to be due to toxoplasma had puzzled pathologists for generations. Her knowledge of ophthalmic pathology has taken her to lecture from Baltimore to Tokyo. She is the first woman to be elected an honorary member of the American

Academy of Ophthalmology and Otolaryngology. Mrs. Wilder is also a member of the American Association of Pathologists and Bacteriologists, which is the only time in the history of that organization that anyone has been accepted without an M.D. degree. The picture shows Mrs. Wilder admiring the gift presented her by the staff of the Armed Forces Institute of Pathology. Mrs. Wilder was recently married to Mr. Roland C. Foerster, and her home will be in San Francisco.

ATOMIC ENERGY COMMISSION

Symposium for High School and College Students.—Twelve of Oak Ridge's senior chemists will go to Atlanta, Ga., on March 5-6 to present an Oak Ridge symposium for college students and promising high school seniors in the Atlanta area. Emory University and Georgia Institute of Technology will serve as hosts for the symposium, the first to be presented by Oak Ridge scientists before a combined high school-college audience. Oak Ridge scientists have become increasingly conscious of an obligation to encourage young people to continue their education, to add to this country's basic strength. The Atlanta conference is an outgrowth of this feeling.

The symposium will be presented by the Oak Ridge Institute of Nuclear Studies and the Oak Ridge National Laboratory. Entitled "Atomic Energy and Chemistry," the symposium has

as its purpose stimulation of the interest of young people in chemistry as a profession. The program will include demonstrations of chemical equipment from Oak Ridge and a motion picture showing how chemistry contributes to the Oak Ridge research program. Among the speakers will be Dr. Clarence E. Larson, director, Oak Ridge National Laboratory, Dr. Ellison Taylor, assistant research director, and Dr. S. C. Lind, director of the laboratory's chemistry division. College students in all Georgia schools north of Macon and from high schools in a 50 mile radius of Atlanta are invited to conference. The first day's proceedings will be held on the Emory campus. The banquet and the second day's program will be held at Georgia Institute of Technology. Blake Van Leer, Georgia Tech president, will preside at the banquet and Goodrich C. White, president of Emory will speak at the opening session.

Oak Ridge National Laboratory is operated for the Atomic Energy Commission by Union Carbide and Carbon Corporation. The laboratory's main activities are in the fields of nuclear reactor development and technology as well as the production of radioactive isotopes for research purposes. The Oak Ridge Institute of Nuclear Studies is a nonprofit educational organization owned by 32 universities, carrying out a program of research and training in the nuclear sciences through a contract with the Atomic Energy Commission.

PUBLIC HEALTH SERVICE

Regular Corps Examination for Medical Officers.—A competitive examination for appointment of medical officers to the regular corps of the U. S. Public Health Service will be held on June 1-3. Examinations will be held at a number of points throughout the United States. Applications must be received no later than April 30. Appointments will be made in the grades of assistant surgeon (equivalent to Navy rank of lieutenant, j.g.) and senior assistant surgeon (equivalent to lieutenant). Appointments are permanent in nature and provide opportunities to qualified physicians for a career in clinical medicine, research, and public health. The requirements for both grades are U. S. citizenship, age of at least 21 years, and graduation from a recognized school of medicine. For the rank of assistant surgeon, at least 7 years of collegiate and professional training and appropriate experience are needed, and, for senior assistant surgeon, at least 10 years of collegiate and professional training and appropriate experience are needed.

The examination will include an oral interview, physical examination, and written objective tests covering the professional field. A copy of the applicant's birth certificate and of transcripts covering all undergraduate and professional education must accompany application forms. Entrance pay for an assistant surgeon with dependents is \$6,017 per year; for senior assistant surgeon with dependents, \$6,918. These figures include the \$1,200 annual additional pay received by medical officers as well as subsistence and rental allowance. Provisions are made for promotion at regular intervals up to and including the grade of senior surgeon (commander) and for promotion by selection to the grade of medical director (captain). Retirement pay after 30 years of service or at the age of 64 is three-fourths of annual basic pay at the time of retirement. Minimum disability retirement pay is ordinarily one-half of annual basic pay at the time of retirement. Additional benefits include periodic pay increases (time served as a member of the armed forces is credited), 30 days annual leave, sick leave, full medical care, and other privileges. Information may be obtained by writing to the Chief, Division of Personnel, U. S. Public Health Service, Washington 25, D. C. Completed application forms must be received in the Division of Personnel no later than April 30.

FOREIGN LETTERS

LONDON

Smokeless Zones.—Both the *British Medical Journal* and the *Lancet* recently discussed smokeless zones. In 1935, Charles Gandy, a Manchester barrister, proposed the principle of smokeless areas as a method of reducing smoke pollution in the industrial towns of England. The National Smoke Abatement Society, of which he was chairman, approached the Manchester Public Health Committee, with the result that the central area of the city was surveyed in 1938 as a first step in the creation of a smokeless zone. The outbreak of war held up the scheme, and it so happened that the area was heavily damaged by air attack. After the war, the area was again surveyed, and it was found that the premises within it, consisting mainly of offices, shops and only a few dwelling houses, had over 2,000 open fireplaces, most of which used bituminous coal. The heating system of many of the buildings had already been modernized, and coal had been replaced by electricity, gas, or coke. This central area was, therefore, deemed to be suitable for an experimental smokeless area.

In a smokeless zone the emission of smoke from any building is prohibited and there are penalties for breach of this rule. Smoke includes the visible and tangible products of incomplete combustion, but not such deleterious gases as sulphur dioxide. Local authorities are always required to contribute to the expenses incurred in making premises smokeless. There is no control over railway locomotives or of some mining processes—a freedom sometimes abused.

The creation of a smokeless zone is not without difficulties. It is essential to obtain the support of public opinion, and persuasion and diplomacy are required to convince owners and tenants of premises within the proposed zone that it will be a good thing for the community and themselves. Expert advice must be freely available so that the conversion of fuel-burning appliances will be the most suitable for particular conditions. Patient explanation must be given to demonstrate that efficiency and economy go hand in hand and that smoke, beside being a nuisance, is in itself a waste of expensive fuel. Serious difficulties arise in relation to industrial operations, but they are not insurmountable.

The results in Coventry and Manchester have been most satisfactory. The medical officer of health for Manchester, has been so impressed with the success of the first year's operation of the central zone that he has already recommended an extension of the zone. The city council has approved, and subject to the consent of the Ministry, the existing zone will be increased to more than double on Oct. 1, 1954. There are still large areas of Manchester left to be made smokeless. Manchester is the nucleus of a congested industrial area of nearly 3,000,000 persons. Although at first sight, to create a smokeless zone of about 100 acres would appear to be a quixotic gesture, with little hope of practical effect, such an effect has been achieved. The center of Manchester is already clearer; the haze of smoke outside the zone contrasts markedly with the absence of visible smoke within the zone. The press has commented favorably on "the hole in the fog." Business houses within the zone have written to the newspapers expressing appreciation of the results; commercial firms outside the zone have asked for extensions to include their premises; public opinion is strongly favorable, and further reduction of atmospheric pollution needs the support of the medical profession.

Need of Physicians' Records.—The problem of whether a physician should give information about his patients baffled a conference on Vital and Health Statistics held recently in London. Delegates (from 28 countries) agreed that it was not

yet possible to make a specific recommendation applicable in all countries and decided that further consideration was necessary. They accordingly proposed that the Expert Committee on Health Statistics continue to study the matter. Vital statistics require extensive use of records, the contents of which are ordinarily safeguarded by professional medical secrecy. Access to such data varies greatly in different countries. It was reported that devices to satisfy secrecy included identifying individual records by number rather than by name and sending such records in sealed envelopes. It was recognized that secrecy could not be kept where, for instance, a person suffering from a communicable disease had to be identified.

The conference was told also that physicians in certain countries had to be protected against the legal and psychological consequences of certifying certain causes of death. Safeguarding professional secrecy was, therefore, in some countries, desirable. Among recommendations made by the conference are those that follow. 1. A detailed census should be held at least once every 10 years. (This is already the practice in Britain, where there has been a census each decade since 1801, except in 1941.) 2. In intercensal years, annual population estimates should be made. 3. Sickness surveys should be carried out and should give the causes of absence from work. 4. In countries with underdeveloped services, mobile medical teams should obtain information. 5. All countries should set up national committees on health statistics. They would help to achieve uniformity in records. This first international conference of its kind was called by the World Health Organization.

MEXICO

Studies on Retinoblastoma.—Dr. Maximiliano Salas of the Hospital Infantil has reported (*Bol. méd. Hosp. infantil* 10: 499-530, 1953) that 49 cases of retinoblastoma have been studied in that institution. In 47 patients the condition appeared in the first five years of life and in 39 it appeared in the first three years. In 8 patients it was noted at birth and in 21 within the first few months of life. None of the patients were over 10 years old. Twenty-four were male and 25, female. The right eye was affected in 16 patients, the left in 26, and both eyes in 7. With the exception of one patient all appeared to have the sporadic type. The histological findings in 33 patients were typical, and the 16 remaining showed variable and nonspecific changes, but with a tendency to form the characteristic histological pattern in certain areas of the tumor. The degenerative changes, such as necrobiosis, necrosis, and hemorrhage, were constant, and calcification was frequent.

In the early diagnosis of retinoblastoma, the pediatrician is of first importance and to make an early diagnosis he should be constantly aware of the disease. With the slightest ocular manifestations, a thorough examination should be made, and, if the condition is found and an operation performed, the chances for recovery are greatly improved. The prognosis in the first period is favorable when the neoplasm constitutes a localized process. The prognosis in the fourth period when dissemination has occurred is extremely grave, and the treatment can be only palliative. Between these two extremes there are many gradations. In the present series, 7 patients died in the hospital and 17 with advanced disease left the institution at the request of their families. This gave a mortality of about 50%. Of the remaining patients, 8 were apparently cured and the remaining 17 were in the intermediate group with a variable prognosis for survival. All patients were given both surgical and radiological treatment. Once a patient has been operated on, the prospects for a second operation giving a beneficial result are poor.

Trichinosis in Mexico.—According to Dr. Luis Mazzotti (*Rev. san. panam.* 35:418 [Oct.] 1953), *Trichinella spiralis* was first identified in Mexico in 1896, by Toussaint, who found it in 13 cadavers he examined at Hospital de San Andrés, in Mexico City. No such investigation was made again until 43 years later, when Perrin in 1939 examined 200 human diaphragms by compression of 1 gm. of muscle and found that 25 had trichinae. Four years later, Mazzotti and Chavira examined 527 human diaphragms in Mexico City and found the parasite in 19. In the same year Mazzotti and Pastrana found that their method in which digestion was used was not as effective as had been thought, because a large number of cysts disappeared under the digestive action of the artificial gastric juice. They therefore continued their studies using only compression of 10 gm. of muscle and found parasites in 57 of 473 diaphragms. The incidence in Mexico is similar to that in the United States, where Wright, Kerr, and Jacobs (1943) found the parasites in 16% of 5,313 diaphragms. Gould (1943) in Michigan examined 357 diaphragms by compression of 10 gm. of muscle and found 29% positive. In 1938 Jacobs using compression only had found parasites in 6 of 100 diaphragms that had previously been studied by the compression and digestion method and were reported as negative. It appears that in Mexico the benign form of human trichinosis predominates and that the severe forms are rare.

NORWAY

Claims Against Physicians and Hospitals.—In 1953 Dr. Jon Björnsson published in a Norwegian law journal a review of the problems raised by accidents leading to claims for compensation against doctors and hospitals. He quoted a study by Dagfinn Dahl covering the period 1932 to 1944, during which one insurance society alone dealt with 162 claims for compensation. Among these claims there were only three that led to action in a court of law. Two-thirds of these claims were settled out of court by the payment of a sum agreed on by all parties, and one-third of the claims were dismissed. Some hospital was involved in 80 of these cases. Since 1944 there has been no great change in the situation, and insurance against claims is now taken out as a general rule by both physicians and hospitals. The natural desire of doctors to avoid publicity in this field and the tendency of law courts to give patients the benefit of the doubt at the expense of insurance societies have led to an unhealthy situation. Dr. Björnsson warned his readers that Norwegian insurance societies may take their cue from certain American societies that have lately refused to handle such claims against physicians and hospitals. Faced by the prospect of heavy damages awarded by law courts, insurance societies are being forced to quote almost prohibitive premiums.

A case quoted by Dr. Björnsson shows how the senior Norwegian public health officer, whose title is "health director," may make his influence felt in a reasonable settlement. The patient in this case consulted a physician for pain in the back. Rheumatism was diagnosed and rest in bed prescribed. When he did not recover, the man saw another physician who took a roentgenogram of the spine, which showed a slight fracture. The patient blamed his first doctor for not having taken a roentgenogram at once. This doctor had, however, not been told that the patient had been exposed to any strain likely to cause a fracture. Besides, pain in the back is so common that it would not be sensible to make it an indication for a radiological examination in every case. The health director explained the situation from this point of view and thus helped to pacify the patient. Dr. Björnsson concluded that many a conflict could have been avoided by the establishment of a more harmonious contact between patient and physician. In Denmark claims against physicians and hospitals are dealt with by a permanent board of medical experts possessing much experience in this field; however, a more casual arrangement exists in Norway with the appointment in each case of medical experts to give judgment.

Cancer of the Lungs.—On Dec. 4, 1953, Prof. Leiv Kreyberg presented a report to the Norwegian Academy of Science on the increase of cancer of the lungs. His material consisted of 233 patients with primary cancer of the lungs, observed over a five year period. After pointing out that as late as 1951 there had been some confusion over the nomenclature, he noted that since then there had been some improvement in this respect, and he was able to distinguish between six types of the disease, each with distinctive features that might help to throw light on its cause. The ratio of men to women for the entire series was four to one. Cases of adenocarcinoma, with a sex ratio of one to one, showed an uninterrupted rise of frequency from the age of 40 to the oldest age group. Professor Kreyberg called attention to a group that included three microscopically distinct subgroups and in which the ratio of men to women was 20 to 1. The age curve in this group was unusual in that the maximal incidence occurred between the ages 50 and 59. There was a slight decrease in incidence between the ages 60 and 69 and a marked fall between the ages 70 and 79. He endorsed Korteweg's views with regard to the lung cancer curve, the contour of which was largely determined by this particular age group.

The lung cancer curve has arisen for the most part in the present century and is the outcome of human action resulting in the occurrence of substances promoting cancer of the lungs, chiefly in men, possibly because of their vocations or their habits. The possibility of a sex factor in this process cannot be dismissed. Much of the rise of the cancer rate in men in Norway (from 15 cases in 1930 to 150 in 1950) probably reflects more accurate diagnosis. It is not likely that the real rate has been more than doubled or trebled in that period. At present cancer of the lungs is the fourth most common form of cancer in Norway; less than 6% of all the deaths from malignant tumors in men are due to it. The corresponding rate in Great Britain is about 25%. Barely half the Norwegian patients with cancer of the lungs have had a history tending to incriminate smoking. An analysis of 127 cases indicates that cancer of the lungs is commoner in Norwegian towns and industrial areas than in the country.

Local BCG Study.—When Dr. J. Heimbeck began in 1927 to vaccinate the tuberculin-negative nurses of Ullevaal Hospital with BCG, he also planned a study of the vaccine in the isolated Sollia district with a population of about 400 at that time. Tuberculin tests of 360 of these persons showed that 172 were positive and 188 were negative. Among these 188 were 147 who consented to the subcutaneous injection of 0.05 mg. of BCG. Thenceforth all three groups (the tuberculin-positive not vaccinated, the tuberculin-negative not vaccinated, and the tuberculin-negative vaccinated) were kept under close observation, the last examination being made by Heimbeck in the spring of 1953. In the *Tidsskrift for den norske lægeforening* for Dec. 15, 1953, Heimbeck published his recent findings. Among the 172 tuberculin-positive persons not vaccinated there was a tuberculosis morbidity of 2.4, a tuberculosis mortality of 1.1 and a mortality from other causes of 11 per 1,000 observation years. Among the 41 tuberculin-negative persons not vaccinated there was a tuberculosis morbidity of 2, a tuberculosis mortality of 1; and a mortality from other causes of 7 per 1,000 observation years. Among the 147 tuberculin-negative persons vaccinated, there was not a single case of tuberculosis throughout the 26 year period, but there were 5 deaths from causes other than tuberculosis. The relatively small number of deaths from causes other than tuberculosis could largely be traced to the persons in this group being younger than those in the first group. Heimbeck's follow-up study also included tuberculin testing in 1953 of the persons who had been vaccinated in 1927. Most of them were still tuberculin positive, but, as several of them had probably been exposed to infection with virulent tubercle bacilli in the interval, the persistence of a positive reaction was not necessarily the outcome of the vaccination. Over the years Heimbeck has learned to distinguish between the comparatively mild tuberculin reaction after BCG and the comparatively violent reaction after accidental infection with virulent tubercle bacilli.

CORRESPONDENCE

RETIREMENT FOR OLDER EMPLOYEES

To the Editor:—In the editorial "Inactivity or Employment for Older Workers" (*J. A. M. A.* 154:242 [Jan. 16] 1954) appears the statement: "The best solution is the creation of a panel to include one or more high level executives and the industrial physician to judge each case on its merits. . . ." In my opinion the presence of management representatives on such a panel is undesirable, as it arouses a sense of suspicion in the employee and among interested union officials. This distrust was apparent when, in 1952 at the request of the U.A.W.-C.I.O., the question of compulsory retirement of employees at age 68 was reviewed by officials of a corporation of which I was then medical director.

After a combined study, a new agreement superseding the existing contract was accepted. The salient features were those that follow. 1. Each union member is asked to report to the medical department for examination and evaluation several months before his 68th birthday. 2. The medical director is furnished data on the employee's job performance, his attendance record, and a detailed description of his job requirements. 3. After examinations have been completed, the medical director recommends either continued employment (at the worker's current job or at one of lesser requirements or reduced hours of work) or retirement. Copies are sent to the employee, personnel department, and the union. 4. If continued employment on the existing basis is recommended and accepted, re-examination and evaluation are carried out annually. 5. If continued employment on a modified basis is recommended but not accepted by the employee, compulsory arbitration is used to resolve the issues. 6. If retirement is recommended, the employee has 30 days to appeal. The union office is notified by copy. If appeal is taken, compulsory arbitration is initiated. In such cases, the arbitrator is a previously agreed on university hospital. Under this agreement the potentially frictional issue of compulsory retirement has been satisfactorily worked out. Nonunion employees and executive personnel should have the advantages of a similar retirement evaluation. I am not, however, aware of any such program currently in practice.

SIMULTANEOUS SIGMOIDOSCOPY AND BARIUM ENEMA

To the Editor:—In *THE JOURNAL* (154:121 [Jan. 9] 1953) Jampel, Dewing, and Jacobson introduced a bold idea in their paper "Simultaneous Sigmoidoscopy and Barium Enema." The authors must be complimented for their courage and for their good intentions, but such courage can only lead to disaster. In the first place a complete sigmoidoscopic examination worthy of the effort must include inspection of the entire mucosa during the withdrawal of the instrument. If this is so, then it would be necessary to reintroduce the instrument for the barium enema. This would make the combined procedure superfluous. Second, leaving the sigmoidoscope in situ and allowing the patient to move from side to back or any other position is extremely hazardous. Sigmoidoscopic and barium x-ray examinations are usually performed on patients with suspected disease in the rectum or sigmoid. Severe injury, if not perforation, can be produced when the patient is moved while the sharp edge of the sigmoidoscope is in close contact with the mucosa. Third, the Sims' position has long been discarded as a satisfactory position for sigmoidoscopy. With the patient in this position, the instrument is difficult to pass, the entire mucosa is difficult to inspect, the physician is in an uncomfortable, awkward posture, and air inflation, which is irritating to the inflamed bowel, is almost always required.

The second to the last sentence of the case report in the article cited states, "The chronic inflammatory indurative process distorted the crypts and columns in the anal canal and

caused multiple fissuring of the crypts and anal skin." How was it possible to inspect the anorectal region during this combined procedure? It is obvious that this description belongs to another examination and that the simultaneous sigmoidoscopy and barium enema cannot be given credit for this finding. Although I respect the attempt, I can see no value to this combined procedure; in fact, it is dangerous, and I for one would not recommend it.

STORAGE AND HOMOLOGOUS SERUM JAUNDICE

To the Editor:—The absence of risk of homologous serum jaundice as shown by J. Garrott Allen and associates (*J. A. M. A.* 154:103 [Jan. 9] 1954) by preservation of liquid plasma for six months is a matter of great therapeutic interest. During the years 1948-1951, I had a similar experience with lyophilized plasma. Sixty containers of Red Cross plasma collected during the war had been left in an abandoned Coast Guard dispensary on Cape Hatteras where the temperatures during the summer reach a subtropical high. Although the expiration date had passed, situations arose in which plasma was needed desperately. All 60 containers of two units each were eventually used. Not a single case of transfusion hepatitis or other complication developed. After this experience, I talked with a medical officer who had served in the Pacific and who, under similar circumstances, had used lyophilized plasma that had passed the expiration date. He also had noted the absence of serum jaundice.

I discussed the possible dangers of the use of such plasma with persons at the National Institutes of Health. They stated that the only possible danger could be the deterioration of the rubber stopper of the containers in which the plasma was preserved. This was minimized by the vacuum in the cans in which the bottles were kept. If this method of prolonged storage were turned to large scale use, it would be a simple matter to have the rubber stoppers changed at the end of two years and under aseptic conditions. It seems, therefore, that prolonged storage of lyophilized plasma under subtropic and tropic temperatures may be a complete preventive of serum hepatitis. While the number of cases are too small to be conclusive, I believe that with Allen's work they point the way to complete prevention of these transfusion reactions.

NORMAN M. HORNSTEIN, M.D.
Southport, N. C.

THE PASSING MOMENT

To the Editor:—In reflecting on the interesting discussions in the recent Leisure Corner, a physician cannot help but try to analyze what is hidden behind this ambiguous term "leisure." Probably one of the most universal interests, especially among physicians, is photography. It seems justified to consider its emotional background in more detail. Perhaps such an approach may lead to a better understanding of the underlying dynamics and nature of leisure activities.

Currently the universal appeal of viewing and taking pictures is so well known and so much taken for granted that we no longer find anything amazing about it. Yet the invention of photography is only about a century old. While the medical and scientific uses are obvious, I am here concerned with the hobby as such. Many outstanding physicians have been and are distinguished amateurs (as in so many other artistic interests). My primary concern here, however, is the examination of why so many enjoy photography who are just simple snapshot fans without much merit. What are the deeper emotional forces that contribute to this widespread appeal and practice? What needs within us are fulfilled by taking pictures? As physicians we cannot help asking for the motives and underlying forces in our enjoyment, of which we certainly have little enough.

A few everyday expressions indicate how deeply imbedded photography has become in our daily lives. To focus attention, to retouch the facts, a blurred picture, the right angle, underdeveloped, to shoot a picture, to hunt for a subject, low key and high key, and to highlight are only a few. Artificial, newly coined words like Kodak and Leica have become as international as OK and dollar.

The universal urge to express ourselves by graphic means, such as drawing and painting, is as old as the history of mankind. The impulse to improve their technical potential was felt centuries ago, as was clearly expressed in the complaint of Lessing: "Would that we could paint with the eyes. How much is lost in the long road from eye to arm to pencil." It is well known from the language of primitive people, children, and dreams that we think in pictures long before we are capable of abstract forms of reflection. Mankind has preserved a universal language of picture symbols without knowing it. But it comes to the surface again even in today's growing desire of the person to express himself and in his increasing interest in personality. Goethe gives this as the reason why confessions, memoirs, letters and anecdotes of long gone, and even insignificant persons are so fascinating. In a deeper sense, both letters and pictures spring out of the same need. It is at this point that the right of the amateur must be reasserted. We are in the very real danger of exaggerating the critical attitude toward all works of art, as though the famous composers and painters had produced only for the sake of a few critics and judges. It cannot be stressed enough that their creative efforts were intended as communications for a specific purpose, a specific occasion, and a specific public.

Today when people no longer write diaries, the snapshots record their lives, as comics, picture magazines, and television replace reading. As a sign of real friendship, people show each other pictures of their early years. We smile when we see them standing before the statue of Lincoln or the Empire State Building, but such a picture satisfies the very real need to hold fast to that very moment—to confirm to themselves that they were once actually there. When we take pictures of people, we cannot help observing their varying reactions. Some immediately take on a conventional set smile, masking their natural expression, while others continue the usual rigid pose. Even national ideals are standardized in the sometimes painfully forced smiles of political leaders that custom dictates.

These considerations already lead us to a deeper analytical level. Hidden there lie forces that express themselves in the photographic urge. Nineteen years ago the late Dr. Wilhelm Lange-Eichbaum (1874-1949), who excelled in psychiatry, chess, writing, sailing, sculpturing, and last but not least, photography, wrote these reflections:

"One takes pictures out of the joy of looking, and also out of a thirst to possess. What has been seen must be had so that you can show it to others, either out of vanity as a hunting trophy (surpassing the rival in competition), or to store away and gather in for the memory of mankind. Furthermore, we take pictures for the thrill of chase and capture, out of desire for mastery of the technical miracle, out of the itch of curiosity. There is a nervous tension before the magic box: Will it come out all right? Also there is the creative joy; one becomes a begetter, a creative artist. Out of chaos, we create a world. Or, one portrays oneself. Technic permits us to make self portraits, thus the beloved eye is mirrored and preserved for all time. In addition, the I becomes expanded to eternity, as well as the spouse, the dog, the house and garden, and again and again, the children. With the mouthpiece of the camera, the ego devours the world like a gigantic snake. Thus the ego swells and inflates itself and becomes greater in its own eyes."

It is not accidental that we talk about "camera addicts," meaning fanatic devotion as miniature camera fans; "specialists" in portraits of men, dogs, flowers, and fashions; color devotees fight for their faith with religious zeal in endless bull sessions. This reminds us at times of the loyalty with which families cling to one make of automobile; for example, "We are a Dodge family". There is often the danger that the recording of an experience may overshadow the experience itself. Shooting the wedding is more important than the wedding itself. At

Yosemite Park, even young persons stare at night at color movies of Yosemite instead of roaming around to discover the beauties of the park for themselves.

The apparent overconcentration on the technical level of new developers, lenses, gadgets, which is elevated at times to a matter of faith, has also a positive value. It is an expression of a fact we tend to overlook; namely, that conscious choice and manipulation are also a primary source of pleasure. Kierkegaard spoke of this in a day when photography was generally unknown, when he observed that "the essence of pleasure does not lie in the thing enjoyed, but in the accompanying consciousness."

Like the motto on the sundial in Venice, we will record only the sunny, happy hours of life, like a receding pinpoint of light as the train of our life roars on through the tunnel of aging. As a person becomes aware of his diminishing vitality, he is anxious to leave a trace of himself after he is gone. Not everyone can leave sons or be a Shakespeare, Rembrandt, Edison, or Frank Lloyd Wright. Then more than ever, he is anxious to hold fast the fleeting moment before it has vanished forever. Who should be better prepared to experience the changing drift of events than a physician? It is, therefore, not incidental that so many physicians are attracted by the hobby of photography. It is not only medical photography, the latest offspring of the rather young art, that fascinates them, but the wide field of the art itself, sharing with our fellowmen the same human dream of everlasting youth, fighting against aging and wasting, by binding time as Joshua did: "Sun, stand thou still upon Gibeon."

Bakersfield, Calif.

STRAMONIUM POISONING

To the Editor:—We have encountered four instances of stramonium poisoning in Philadelphia. Four Negroes, 16 to 38 years of age, each drank approximately 200 ml. of a "strong tea" prepared as a cold cure from Jimson weed (*Datura Stramonium* Linné) as identified by Drs. John Fogg and H. A. Wahl. The symptoms of toxicity developed within 30 minutes in each case and were very severe in all but one. They included nausea, vomiting, dizziness, loss of balance, incoordination, transient blindness, unconsciousness, and bizarre visual, auditory, and tactile hallucinations. These hallucinations, present in three of the four, were marked by extremely vivid overlays of color, particularly of red, but also of other colors throughout the visual spectrum. The patients came to the hospital for treatment 21 hours after the onset of toxicity. By that time the symptoms had considerably abated, although three patients continued to report dizziness and marked, variable abnormalities of color perception related at times to mild hallucinations. At least once, two concurrently reported the same hallucination. On physical examination all had markedly dilated pupils that reacted sluggishly to light; none exhibited mucous membrane dryness; and all denied previous dryness, thirst, or polydipsia (although two asked for water). Two had systolic and diastolic blood pressures in the upper range of normal, and the pulse rates were normal or slightly elevated. One showed a slight horizontal nystagmus and head shaking and one a mild intention tremor. Three had slight hyperreflexia and a slight tendency to maintain fixed positions. Temperatures were not taken. The examination was otherwise essentially normal. All the patients were sent home without therapy. Recovery occurred during the following few days.

The weed in this case was picked, four years earlier, in Augusta, Ga., for use, through the inhalation of its smoke, in the self-treatment of asthma. This is apparently not an uncommon practice in rural areas. Hughes and Clark presented a detailed review (*Stramonium Poisoning: Report of Two Cases, J. A. M. A. 112:2500 [June 17] 1939*) of stramonium poisoning, including the amusing report of several cases that occurred in Virginia in 1676.

COUNCIL ON MEDICAL EDUCATION AND HOSPITALS

The publication of the following information concerning the provision for graduates of foreign medical schools as interns and residents in United States hospitals through the Exchange Visitor Program of the Department of State has been authorized by the Special Services Division, International Educational Exchange Service, Department of State.

Any hospital that is approved by the Council for intern and/or resident training may participate in the Exchange Visitor Program and may appoint graduates of foreign medical schools to its intern or resident staff without prejudice to its approved status. Responsibility for the evaluation of the applicant's qualifications must be assumed by the hospital, however, in those cases in which the applicant is a graduate of a school other than those included in the list prepared by the Council in collaboration with the Association of American Medical Colleges (THE JOURNAL, Sept. 12, 1953, page 133).

EDWARD L. TURNER, M.D., Secretary.

MEDICAL TRAINING UNDER EXCHANGE-VISITOR PROGRAM ARRANGEMENTS

Arrangements for admission of foreign medical students to serve internships and residencies in American hospitals are currently made in accordance with the Exchange-Visitor regulations promulgated under provisions of Section 201 of the United States Information and Educational Exchange Act of 1948, as amended. These regulations provide for the granting of Exchange-Visitor visas to various types of exchange visitors such as trainees coming to the United States to obtain practical training in public administration, industry, medicine, agriculture, or some other specialized field of knowledge or skill. Such visas can be issued, however, only to persons who have been selected by sponsors of programs that have been designated as Exchange-Visitor Programs by the Department of State.

American hospitals interested in providing medical training opportunities to foreign nationals are advised to establish Exchange-Visitor Programs under which qualified trainees may be selected as participants. Exchange-Visitor Program application forms (Form DSP-37) and information concerning the filing of such applications may be obtained from the Special Services Division, International Educational Exchange Service, Department of State, Washington 25, D. C. Prospective sponsors of medical training programs should be able to furnish evidence of their accreditation or approval by an appropriate board or agency for the training they wish to offer to foreign nationals. Under current regulations and policies the State Department requires this information as a prerequisite to designation of such a program. The agency or institution sponsoring an Exchange-Visitor Program is responsible for the selection of the foreign nationals who may be admitted as participants to engage in the activities provided in the designated program under its sponsorship. The department does not approve or confirm selection of participants under private sponsorship.

Although no change in status from that of Exchange-Visitor can be authorized under the Exchange-Visitor regulations, the transfer of an exchange visitor from one designated program to another may be effected if the alien's sponsor approves such a transfer and considers the arrangement to be consonant with the purpose for which the alien was admitted to the United States. A request for such a transfer should be made by the exchange visitor at the district office of the Immigration and Naturalization Service nearest his place of residence in the United States and must be supported by written evidence of his release from the program in which he is a participant as well as a letter affirming his selection as a participant in the designated program to which he wishes to transfer.

With respect to the staffing of American hospitals and institutions with foreign physicians or the need that such institutions may have to recruit assistance from foreign sources, recourse to other than Exchange-Visitor Program arrangements is available. Institutions desiring to employ foreign nationals temporarily may apply to a district office of the Immigration and Naturalization Service for authorization to import such persons under the provisions of Section 101(a) (15)(H) of the Immigration and Nationality Act. Further information concerning this procedure may be obtained from the nearest district office of that service.

MISCELLANY

THE DEATH OF PRESIDENT LINCOLN

"On the evening of Friday, April 14, I was summoned in haste to the late President of the United States, to whom I had the honor to be family physician. . . . [He] had been carried to the residence of Mr. Peterson, who resided on Tenth Street, opposite the scene of the deplored slaughter. . . . I found my friend, Assistant Surgeon Taft [and others] supporting the sufferer's head. . . .

"The case was surrendered to my care and I proceeded to the exploration of the wound. The President . . . lay, perfectly passive on his back as if quietly asleep, without any distortion of feature—though at times his respiration was somewhat stertorous. Examination showed that he had received a gun shot wound on the posterior aspect of the head—not far from the median line and about three inches from the left auditory meatus. . . . [His] left eye was blackened—the . . . orbital surface was ecchymosed. . . . The pupil of the right eye was very much dilated and immobile. The left pupil was unchanged, or if anything was myotic or diminished. . . . While engaged about him, rendering all the aid in our power, I noticed the appearance of a . . . purple spot at the internal angle of the right eye—This . . . gradually increasing in size, crowding the whole orbital periphery until the right eye was surrounded by a zone of the most intense ecchymosis. This gradually increased [and] the effusion was forced into the subconjunctival . . . tissue. . . . The ball of the eye became prominent by slow degrees until the zone around the . . . orbit was complete, and . . . the ball seemed to protrude one inch at least from its socket. After a short time, when the intensity of the left orbital ecchymosis had reached its [maximum] . . . the left pupil began to . . . dilate, until the dilation of both pupils was equal.

"When I first reached the . . . President, he was breathing quietly and calmly and I had hoped, he had received a less fatal injury, but in a few moments, his breathing became difficult and stertorous. On examining the wound, it was found that the orifice was plugged by coagula and debris of brain tissue. On cleaning this away, the wound bled steadily though not severely and instantly almost the stertor was removed and respiration became . . . regular. . . . The wound . . . gave the appearance of having been produced by a larger ball than that used in an ordinary revolver or pistol. The hair of scalp was not in the least burned—the edge of the wound was sharp and distinct. On probing the wound with the finger the projectile was found to have cut a distinct and perfectly round aperture . . . totally devoid of spicules of . . . either table of the injured occipital bone. . . .

"With a small silver probe, I attempted to follow the ball and recognized the pressure of a rough foreign body, whether bone or a fragment of ball, it was impossible to determine. Some inches further on, a larger body of the same character

From pen and ink manuscript written by Dr. Robert K. Stone, Lincoln's personal physician. This manuscript is in the collection of Dr. Max Thorek, Chicago, Ill.

was touched and passed, and the probe passed its full length without giving the . . . sensation of striking a metallic body. A longer . . . probe was procured by my friend, Dr. Taft, and with this, I proceeded to re-explore the track of the wound. The course of the wound with this . . . instrument was found to be forwards, upwards with a decided inclination inwards. The two foreign bodies already alluded to, were noticed and passed and the probe . . . struck against what, at first seemed to be the ball. But further exploration convinced me that I was striking a fractured bone. . . .

"During the evening the President's state varied. . . . We . . . had [a] large sinapism made and laid over his abdomen and extremities and as in a little time the mustard [was] found to have been useless . . . a new set of strong fresh sinapisms were prepared and his body and limbs enveloped in them. Bottles and jugs of hot water were placed near him and his extremities, to regulate the temperature. . . . All aid was useless [and] . . . we had to wait for the slow exhaustion of that vital energy, which a few short hours ago had promised so many years yet to come of happy life and goodness to all men. . . .

"The amount of brain tissue broken up and discharged from . . . the wound . . . must have been considerable. The gentlemen who were present and aided to remove the President to Mr. Peterson's house [said] . . . that much brain was lost in transporting the body across the street. During my presence, the loss of brain substance was considerable for the ball orifice was . . . evidently produced by a large projectile. At times when seated by, counting the pulse, I noticed that the stertorous breathing became very distressing and the flow from the wound was almost null. Suddenly there burst forth from the wound, on several occasions small masses of brain and coagula . . . followed by a gentle steady trickling of blood. This phenomenon was always productive of the greatest improvement—The respiration and pulse were instantaneously improved. It is impossible to say how much cerebral substance was lost. . . . The loss of blood was not very great, at any one time, but was steadily continuing in a gentle drain—unless when coagula and brain debris arrested the flow and then the stertor and labored breathing were distressingly painful to witness and its flow was at once [stimulated, thus] . . . prolonging life and depriving death of some attendant horrors, which would needlessly have harrowed the soul of the relatives and friends who . . . witnessed the passing away of this great man. . . .

"The next day previous to the process of embalmment, I proceeded to the autopsy of our late President. . . . Before proceeding to the autopsy, we noticed that the ecchymosis of the whites of eyes was very intense and had passed to the temples and malar surface. The right eye had lost its protrusion as heretofore described and again, fell back to its usual position. . . . On the occipital portion of the head . . . there was great . . . edema about the wound and some extravasation of blood. . . . The wound itself, seemed a clean cut gaping slit through the scalp—in the occipital bone itself, the ball orifice was a clean cut circular opening singularly free from all splinters . . . and appeared as if it had been cut through the bone, with a sharp punch—between the scalp and the bone orifices, we removed a little shaving of lead, which had evidently been pared from the ball, as it drove through the harder tissues.

"We . . . [divided the] scalp from ear to ear and [sawed] off the calvarium. When the scalp was removed we found that the ball had passed the occipital bone one inch to the left of the median line and had traversed the upper edge of the left lateral sinus a little to the left of the torcular Herophili. This wound in the occipital bone was remarkably smooth and . . . spherical in shape and bevelled off from without inwards so that the aperture of the internal table of cranium was decidedly larger than that of the outer table. Thence passing forward . . . the ball pierced the dura mater and through posterior lobe of the left hemisphere of the brain. Thence . . . it entered the left lateral ventricle of the brain behind

. . . ploughed the upper part of the thalamus . . . and lodged in the white cerebral substance just above the corpus striatum of the left side.

"In the track of the ball, the brain was in a pulpy disorganized state and around the track was pultaceous and livid from capillary hemorrhage. About 2½ inches in the track, within the orifice of the wound, the first piece of occipital bone . . . driven in by the ball was discovered. A second and larger fragment of the bone was discovered, further forward, about 4 inches within orifice, and the ball still further in. The track of the ball was filled with coagulated blood. . . ."

MEDICAL MOTION PICTURES

Some Aspects of Accessible Cancer: Part II—Lip, Tongue, and Mouth: 16 mm., black and white, sound, showing time 25 minutes. Produced in 1951 by Realist Film Unit, London. Principal advisors: Christie Hospital and Holt Radium Institute, Westminster Hospital. Procurable on loan (\$10.00) or purchase (\$90.00) from British Information Services, 30 Rockefeller Plaza, New York 20.

The quiet symptomless beginnings of squamous-cell epitheliomas in the lip, tongue, and mouth and the essential curability of these early lesions are stressed. The diagnosis and treatment of an early case of carcinoma of the lip by radium mold is shown, followed by a more advanced case treated by implantation. Radium implant for cancer of the tongue and surgery in which the lymphatics are involved are demonstrated. Methods of irradiating other cancers of the mouth with radium or roentgen-rays are also shown. Statistics are given to prove how much better the prognosis is when treatment is given early. This motion picture conveys a realistic picture of radiation therapy as it is now being carried out in England. From the standpoint of American specialists in head and neck carcinoma, there is far too much emphasis on radiation as against surgery; however, it would be of interest to specialists in this country as an illustration of currently used methods of therapy in England. The film is well organized, and the photography is excellent.

Some Aspects of Accessible Cancer: Part III—Larynx: 16 mm., black and white, sound, showing time 24 minutes. Produced in 1951 by Realist Film Unit, London. Principal advisor: the Royal Cancer Hospital. Procurable on rental (\$10.00) or purchase (\$90.00) from British Information Services, 30 Rockefeller Plaza, New York 20.

Photographs of tumors of the vocal cords as seen laryngoscopically are shown, and the help given by x-ray photographs is discussed. Treatment of the early case is by radiotherapy, but surgical extirpation is required for a more advanced growth. The highly effective esophageal voice that these patients can learn to produce is explained and demonstrated. This film stresses radiation and also surgery after radiation but not surgery alone. Although the emphasis on radiation therapy does not represent the consensus of opinion in this country, the film is of interest as an illustration of the British method of treating cancer of the larynx. The black-and-white photography is satisfactory.

Some Aspects of Accessible Cancer: Part IV—Breast: 16 mm., black and white, sound, showing time 28 minutes. Produced in 1951 by Realist Film Unit, London. Principal medical advisors: Westminster Hospital and the Royal Cancer Hospital. Procurable on rental (\$10.00) or purchase (\$90.00) from British Information Services, 30 Rockefeller Plaza, New York 20.

Any lump in the breast, however small and painless, must be taken seriously, and certain simple methods of examination are explained and demonstrated. Confirmation of diagnosis in the operating theater by frozen section of a suspicious tumor is shown, followed by radical mastectomy. A number of advanced cases are also illustrated, and the possibilities of radiotherapy, with or without surgery, are discussed. Hormone therapy is mentioned, and there is a brief section on carcinoma of

the male breast. This film is a review of the advantages of early diagnosis and definitive treatment as these have been observed in England. It gives in detail the technique of biopsy, examination for localized carcinoma, and the definitive operation. The discussion and representation of moderately and far-advanced carcinoma tend to stimulate the effective use of palliative treatment by radiation, surgery, and hormones. The statistics cited and the surgical philosophy are essentially the same as those in the United States. This motion picture is well organized and well presented, and the photography and narration are excellent. It is recommended for showing to medical students, residents, and interns.

Some Aspects of Accessible Cancer: Part V—Cervix and Uterus: 16 mm., black and white, sound, showing time 35 minutes. Produced in 1951 by Realist Film Unit, London. Principal medical advisors: Chelsea Hospital for Women, Christie Hospital, and Holt Radium Institute under the general supervision of Sir Stanford Cade, F.R.C.S., Malcolm Donaldson, F.R.C.S., and Dr. G. F. Stebbing. Procurable on rental (\$10.00) or purchase (\$90.00) from British Information Services, 30 Rockefeller Plaza, New York 20.

The potential seriousness of intermenstrual and postmenopausal bleeding in women over 40 is emphasized, and the patient's tendency not to take it seriously because it is painless is also pointed out. Methods of examining the cervix are shown and methods of radiotherapy explained and demonstrated. The greatly improved results of treatment at an earlier stage are contrasted with the high mortality later. The importance of curettage and histological examination for carcinoma of the body of the uterus is stressed. Surgery is the treatment of choice, and panhysterectomy with removal of tubes and ovaries is shown. The value of preoperative radiotherapy is also discussed. It is pointed out that by early diagnosis and treatment the mortality could be halved and that careful follow-up and early treatment of recurrences is often successful. This is an excellent teaching film and is recommended for general practitioners and medical students. The photography is well done.

NEW FILM ADDED TO A. M. A. MOTION PICTURE LIBRARY

America's Untapped Asset: 16 mm., black and white, sound, showing time 13 minutes. Produced in 1952 by Universal Pictures with the cooperation of the United States Employment Service, Office of Vocational Rehabilitation, Veterans Administration, and the Bankers Life and Casualty Company. Procurable on loan from Committee on Medical Motion Pictures, American Medical Association, 535 North Dearborn Street, Chicago 10, or President's Committee on Employment of the Physically Handicapped, 260 Madison Ave., New York.

This interesting film delivers its message very effectively. Its primary purpose is to persuade employers to hire the physically handicapped and to indicate that there are many types of employment in which the handicapped person can work just as effectively as, or sometimes even more effectively than, a normal person. The photography and the narration are all very good. The film starts with a record of an address given in Washington, D. C., on Sept. 23, 1953, by President Eisenhower to a group of approximately 2,000 persons, including members of the President's Committee on Employment of the Physically Handicapped. In this address, the President mentioned that there are many committees that carry the title of the "President's Committee." He said, "There is none that engages the interest of my heart, or of which I am prouder, than this one." The President mentioned an experience that he had had during World War II, when he requested of General Marshall the services of a fine corps commander. General Marshall replied that he agreed that this man was an excellent leader but that he had arthritis of the knees and he was afraid he could not get medical clearance for him. The President then replied, "Please send this man right away, quickly. It is his head and his heart I want, and I will carry him to battle in a litter. But a man, even though he has arthritis in the knees, is still fit to do the job I want." The President then concluded, "I am trying to show you that we can, after all, even in war, overemphasize this question of complete physical

normalcy. Incidentally, you will be glad to know the sequel, which was that that man led his corps brilliantly throughout the rest of the war and fully met every expectation that I had of him."

The film then goes on to develop the President's theme that a person who is disabled insofar as one function of the body is concerned can still perform brilliantly and is frequently able to overcompensate for his disability so that such persons are "ready, willing and able to work" and have demonstrated that "it is good business to hire the handicapped." A series of rapid views of the methods of medical rehabilitation of the disabled are given and then the major portion of the film is devoted to showing how more than 600 disabled persons have built up a good record as employees of the Bankers Life and Casualty Company. Deaf mutes are shown as excellent messengers who do not stop to converse with their associates. A deaf woman is shown doing paper work next to a person with normal hearing and working with equal efficiency. A one-armed secretary is depicted performing her various duties with great ability. A one-armed man is shown operating a complicated electronic machine, and a keen-eyed, gray-haired woman is shown operating a complicated machine with great rapidity. It is mentioned that this woman began her work at the age of 78, seven years ago! The film ends with a plea for everyone to cooperate with the President's Committee on Employment of the Physically Handicapped and states, "Hire the handicapped, it's good business."

All physicians and health workers who are interested in the employment of the handicapped should urge wide showing of this film among service groups and groups of employers.

BUSINESS PRACTICE

The following material is based on a public relations manual issued by the Public Relations Department of the American Medical Association.—ED.

SCHEDULING APPOINTMENTS

Mrs. Leslie hired a baby sitter so that she could come to see the doctor. She was kept waiting two hours. John Brinks, vice-president of a local company, missed an important committee meeting because he had to wait to see the doctor. The physician was not entirely to blame. He had been called away on an emergency, and his secretary had scheduled his appointments too closely. An appointment with the doctor is important to the patient; if he has to wait a long time, he becomes irritated and resentful. A recent survey showed patients complain twice as much about long waiting as about fees.

Even though emergencies make it difficult to eliminate all waiting, most physicians can cut unnecessarily long waits by practicing efficient scheduling of appointments. A waiting room costs money in terms of rent, furnishings, and upkeep. Today the trend is toward a smaller reception room, because more doctors are seeing patients on an appointment basis. A professional management official reports that a physician who switched to the appointment system saw one-third more patients in a month's time than previously but was not aware of it because he did not "feel pushed." Patients without appointments should be worked into the schedule if possible, but the physician or his assistant should say something like this: "The doctor will be able to see you this time but would appreciate your making an appointment the next time you come in." Patients soon learn that appointments save their time too.

Home calls should also be scheduled efficiently. A physician should urge patients to come to his office for treatment when possible, pointing out that the facilities for the best medical treatment are available there and that office calls are more

economical. One doctor's assistant routes his home calls by means of a large city map, thus saving him time that might otherwise be lost in aimless searching for streets and houses and in backtracking.

Efficient scheduling of appointments reduces strain on the physician and increases his ability to give his patients the best medical service. He should arrange office hours to fit community needs. Some doctors hold evening office hours two or three times a week for the convenience of working patients. All appointments should be scheduled with tact, patience, and finesse and should convey the impression that the doctor is trying to arrange a time when he can give the patient his complete attention. The appointment book should be marked off into time intervals. On the basis of past experience definite amounts of time should be allowed for first visits, check-ups, and other procedures. The schedule should be adjusted to fit the type of practice. Conflicting appointments should not be made, and the schedule should not be overcrowded. Two or three vacancies should be reserved during the day for catching up or as "breathers." House calls should be scheduled realistically at hours not conflicting with office hours. Referred patients and patients without appointments should be fitted into the schedule as judiciously as possible. Some physicians leave late afternoon and early evening appointments open for patients needing immediate attention. If it is necessary to refuse an appointment, a reason should always be given. When an emergency takes the doctor out of the office, the situation should be explained to waiting patients, giving them the choice of waiting or of making a new appointment. If it is necessary to cancel an appointment, the patient should be notified and a new appointment made. Patients should always be given a written or oral reminder of their appointment.

If patients are kept waiting long, they are due an explanation. The doctor or his assistant should make it clear that they are keenly concerned about the delay. When the doctor is unexpectedly called out of his office, his receptionist should say something like this: "Dr. Black has been called out of the office on an emergency. It may be an hour or so before he returns. He is very sorry to inconvenience you and asked me to inquire whether you want to wait or would like a new appointment. Perhaps you would like to shop and come back in an hour. I feel sure the doctor will be able to see you then." The patient's time is valuable too!

THE LEISURE CORNER

PLASTIC MODELS

Building really authentic models of ships, airplanes, automobiles, railroad cars, and similar objects requires intense concentration and an infinite amount of detailed, precise labor. Too deep a cut by the knife, a slip of the paint brush, and the model is ruined. After a while, this hobby may begin to take on an uncomfortable resemblance to work, fairly tedious and frustrating work at that. The manufacturers of plastic model kits have attempted to put the satisfaction back into hobby construction. Plastic model kits require no tools and no carving, cutting, or sanding. They can bring the pleasures of authentic model construction to those with limited manual skills as well as those with creative talents. Most physicians, of course, are skilled in the use of their hands, but time, a commodity especially rare in the life of a doctor, makes it almost impossible for him to devote to the hobby the days and weeks of intense and painstaking effort it takes to create an authentic model. Professional duties force him to postpone work on his hobby, and when he is able once again to settle down to it, it may be difficult to regain that first flush of enthusiasm. With plastic kit modeling, however, the physician or other hobbyist can, in a matter of hours and minutes, create a perfectly detailed replica

at about the cost of a dollar, not an unimportant consideration when the cost of pursuing some hobbies runs into hundreds of dollars.

The designing skill and the degree of precision engineering that a manufacturer puts into his plastic model kits determine their authenticity. One of the most exquisitely detailed models on the market today is the reproduction of the famous United States battleship, the Missouri. In making the model, the manufacturer created a 20 in. replica of the Missouri from actual U. S. Navy blueprints. It is cast in plastic with a one-piece hull and a one-piece deck that fits on top. Simply by adding the superstructure and other topside details, the hobbyist ends up with an absolutely precise model of the "Mighty Mo," which would bring joy to the heart of even the most accomplished professional model ship builder. For example, the accurate stem-to-stern details even include exact replicas of the tiny flags that flutter in the breeze high above the decks. This same company has "commissioned" virtually an armada of U. S. Navy fighting ships. The fleet includes the Missouri; the revolutionary Nautilus, the first atom-powered submarine; a patrol torpedo boat; a Fletcher Class cruiser; and a Baltimore Class cruiser. Should the "skipper" wish to get away from it all and indulge in a bit of luxury, there is a Chris Craft double cabin cruiser, which his talent can recreate. Precision engineering has made each ship a perfect reproduction. For example, engineering on the Nautilus is precise to the point of including a clear plastic housing on top of the conning tower, finely designed dual radio and radar antenna, attack periscope and snorkel, stabilizers and indicated torpedo ports in bow, deck grooving, hatch covers, elevators, rudder, and propellers at stern.

One of the unusual features of all these models is the inclusion of human figures in realistic positions and costumes. An alert has apparently been sounded on the patrol torpedo boat, for its men are at their battle stations ready to fire three 20 mm. machine guns and two 50 caliber twin engine aircraft guns.

The range of model subjects has grown to include reproductions of old-time sailing vessels, which can be slipped into bottles as attractive display pieces; replicas of the early covered wagons that first crossed the western prairies; smooth, sleek jet fighter planes, such as the Lockheed Starfire—the completely automatic Army plane, the Chance-Vought Cutlass—the Navy plane with dual turbojets and dual rudders, and the Grumann Cougar—the primary ship of the Marine flying corps. The Lockheed model is cast in aluminum plastic, has two miniature pilots, clear canopy, full color decals, and molded insignia.

Probably the most well-known of all plastic model kits are the Highway Pioneers, a series of authentic replicas of antique automobiles, such as the famed 1913 Maxwell, the 1911 custom-made Rolls Royce, the 1904 Oldsmobile, the 1903 Model "A" Ford, and the colorful 1914 Stutz "Bearcat," seen on virtually every university campus during its heyday. Naturally, no car is complete without its driver; thus a collegiate young man, mustached and becaped, sits at the wheel attired in a racoon coat. The company manufacturing antique automobiles produces 15 turn-of-the-century models, each equipped with a driver dressed in the fashion of his day. As all of the parts are premolded, the irritations involved in precision carving, whittling, and cutting are avoided. All that is needed is the ability to work with a tube of cement.

Many physicians have found modeling of such kits to be an excellent diversion for convalescing patients. Without undue effort, they are able to remain pleasantly and fruitfully occupied. Comment by thoughtful visitors on the rapid progress the patient is making in his hobby construction can be an invaluable morale booster. Plastic models lend themselves delightfully to attractive displays not only in the home but also as cheerful decorations in the physician's waiting room. The model maker can give his old-time cars a museum look by enclosing them in prefabricated clear plastic cases or he can display them as parts of book ends or name plates or as mantlepiece decorations. Plastic kit modeling affords a means of relaxation and enables father and son and the rest of the family to work together, jointly sharing and taking pleasure in the same hobby.

Cathode Rays for Lymphomas.—During the past two years the authors treated five patients having lymphomas with extensive involvement of the skin who had not responded to any other form of therapy, one patient with inner canthus carcinoma, one with atopic dermatitis, one with syphilis barbae, and three patients presenting keloidal scars. These patients were all treated by delivering to the involved skin area a number of doses of 2,500,000 volt electrons, these electrons being produced by a constant potential accelerator of the Van de Graaff type and projected into air toward the skin of the patient as a directed stream of particles. Of the five patients with mycosis fungoides, all but one received symptomatic relief from their skin lesions. The patient failing to receive palliation was one with advanced lymphoma and multiple nodes in the axilla and groin. All other patients have shown healing of their lesions, whether of the psoriasiform type or of the infiltrative tumor and ulcerated type. One patient whose disease was localized to the forearm received only one series of treatment, and the relief has been satisfactory for 16 months. The other patients had no untoward effects on their skins within an observation period of from 6 to 12 months. In two patients, a moderate to severe pancytopenia inexplicably developed; this condition was amenable to therapy. The superiority of cathode rays for the treatment of superficial malignant lesions lies in the unique ability to localize their ionizing energy so as to avoid both the irradiation of under-

lying tissue and the excessive irradiation of the radiosensitive skin. The optimum localization is attained when the high energy electrons enter normal to the skin surface and when they are of approximately the same energy. A further advantage of cathode ray therapy is that the depth of penetration can be controlled by adjustment of the accelerating voltage.

Quinacrine in Lupus Erythematosus.—During 1952, the authors treated with quinacrine (Atabrine) hydrochloride 60 patients with lupus erythematosus. Of these, 55 had the chronic discoid form of the disease and 5 had moderate systemic manifestations of lupus erythematosus. Thirty-nine patients were women, and 21 were men. Most of the patients had had the disease for many years prior to treatment with quinacrine, and only eight had not received previous therapy with gold, bismuth, arsenic, quinine, various hormones, and carbon dioxide snow. Of the 55 patients with the chronic form of the disease, 52 were followed to April, 1953. The following results were obtained: 11 patients were either not or up to 25% improved (1 reported that he was worse); 9 were 25 to 75% improved; 15 were more than 75% improved, but the disease was not arrested; and 17 had complete arrest of the disease. Twenty-one of the patients had discontinued taking quinacrine; 10 of them had recurrence and 11 no recurrence. The recurrences appeared after periods varying from two weeks to over six months. The incidence of ill effects was low, and it is noteworthy that this series of patients with lupus erythematosus showed that perceptible transitory yellowing of the skin, though a frequent effect of quinacrine and other therapy, is not a requirement in the production of good results. This is contrary to the prevalent opinion, which assumes that yellowing of the skin indicates the presence of fluorescence, the supposed efficient mechanism by which quinacrine relieves the symptoms of chronic lupus erythematosus. The authors state that a demonstrable fluorescence may be present long before the skin becomes yellow; and they also emphasize that the actual mechanism by which the drug exerts its influence is still unknown. Quinacrine is a valuable therapeutic agent in lupus erythematosus, except in patients with widespread cutaneous manifestations of the disease and patients in whom there is also laboratory evidence of the systemic type.

Splenectomy in Acute Systemic Lupus Erythematosus.—Recent work has attempted to define the physiology of the normal spleen. Johansen demonstrated in 1950 that the spleen, instead of secreting a hormone that inhibits the bone marrow, as was thought formerly, actually resorbs a factor that normally promotes the function of the bone marrow. The relation of altered physiology to the commonly accepted hypersplenic syndromes and to some conditions not thus commonly classified has been studied, but the resulting contradictory conclusions have not been clarified. There is, however, an increasing tendency to consider hypersplenism as an exaggeration of one or more of the normal functions of the spleen, thereby producing a pathological state. The results are presented of 12 splenectomies performed on patients acutely ill of systemic lupus erythematosus in Honolulu during the past seven years. In the first two, the disease was complicated by thrombocytopenia, and response to splenectomy was dramatic. The other patients showed favorable clinical and hematological changes. Splenectomy may usually be relied on permanently to eliminate thrombocytopenia, leukopenia, or acquired hemolytic anemia from the clinical picture of systemic lupus erythematosus; and the procedure is indicated when any of these manifestations are sufficiently severe to threaten the patient's well-being. The operation may be followed by a remission of systemic lupus erythematosus, but this may be no more than a temporary improvement.

Periodicals on file in the Library of the American Medical Association may be borrowed by members of the Association or its student organization and by individual subscribers, provided they reside in continental United States or Canada. Requests for periodicals should be addressed "Library, American Medical Association." Periodical files cover only the last 11 years, and no photoduplication services are available. No charge is made to members, but the fee for other borrowers is 15 cents in stamps for each item. Only three periodicals may be borrowed at one time, and they must not be kept longer than five days. Periodicals published by the American Medical Association are not available for lending but can be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them.

Titles marked with an asterisk (*) are abstracted.

Cortisone and Corticotropin in Systemic Lupus Erythematosus.—A survey is presented of 83 observed patients with positive plasma L. E. tests for systemic lupus erythematosus. Only 10 of them had not been treated with steroids (cortisone, hydrocortisone acetate, or corticotropin), since the first use of steroid therapy followed so closely the development of the L. E. test. There are two principal points on which the natural course of systemic lupus erythematosus can be compared with the course affected by steroid treatment: the length of time between the onset of symptoms and death, and the interruption of a rapidly lethal course. The L. E. test has revealed the fact that the disease may have an early latent phase without obvious symptoms and has therefore lengthened the possible overall duration of systemic lupus erythematosus to 90 months, against the estimate of 52 months made before the L. E. phenomenon was known. With this knowledge in mind, Haserick estimates that steroid therapy used without interruption over a long period of time has prolonged the life of a significant number of patients. The dosage used to maintain the remissions varied according to the individual requirements of the patients from 10 units of corticotropin to 100 to 125 mg. of cortisone acetate per day. Steroid therapy also occasioned an improvement in morbidity in some of these patients, enabling them to lead more normal lives and protecting them from certain infections that tend to complicate systemic lupus erythematosus. The dramatic lifesaving effect of steroids on a severe fulminating course of the disease is well established. Some patients, especially those with progressive renal disease, did not respond to steroid therapy, and some who had remissions discontinued steroid therapy, with disastrous results. The physician should be warned of this eventuality.

Genetic Aspects of Multiple Sclerosis.—Of 750 patients with multiple sclerosis treated at two hospitals in Sweden in the course of 25 years, 27 (3.6%) had close relatives (parent, sibling, or child) with multiple sclerosis. Four of the 27 probands had two affected relatives, and 23 had one affected relative. Several of the probands were consanguineous. The 27 probands with an affected relative were thus distributed among 16 families. Of the 27 probands, 14 were women and 13 men. There was also a slight excess of women in the whole series. In 14 of the 27 probands the age of onset was less than 25; in 2 the onset of the disease was after the age of 40. In the entire series, 52% of the probands became affected before the age of 25, and 8% after the age of 40. The incidence of the disease in the probands' parents was $0.3 \pm 0.15\%$, in the siblings $1 \pm 0.21\%$, and in the children $2.3 \pm 1.15\%$. The calculations were based on Strömberg's "exact" method. The incidence of the disease in all the observed relatives aged over 9 years was $0.6 \pm 0.11\%$. The extent to which different genetic hypotheses are in agreement with the morbidity rate in the close relatives of the probands was investigated. The available data gave no support to the concept that genetic factors are active in multiple sclerosis.

Health Hazards Among Troops Returning from Korea.

After briefly listing diseases that were expected but not encountered in Korea, Hunter discusses the diseases that did occur; respiratory infections, venereal disease, diseases of the intestinal tract including diarrhea and dysentery and intestinal parasites, and the arthropod borne diseases such as Japanese B encephalitis, epidemic hemorrhagic fever, and malaria. He arrives at the conclusion that, from the standpoint of public health, there seems to be little danger of the introduction of transmissible diseases from Korea to the United States. The incidence of intestinal worms in U. S. Army veterans of the Korean campaign appears to be somewhat higher than elsewhere in the Far East. However, the density of the infection in any person is low and so should not constitute a public health problem. Malaria constitutes the greatest risk, but in view of the record it is believed that the calculated risk is minimal, provided adequate mosquito control is maintained.

Bilateral Resection in Pulmonary Tuberculosis.—Bilateral pulmonary resections were made in 3 male and 14 female patients who were between the ages of 16 and 45 and had pulmonary tuberculosis. The tuberculosis was classified as minimal in 4, moderately advanced in 1, and far advanced in 12 patients. The sputum was positive for acid-fast bacilli before the first operation in all but one patient, and 14 had sputum positive for tubercle bacilli between the first and second resections. Thoracoplasty failure constituted the indication for three of the operations, pneumothorax failure for seven, a destroyed lobe previously untreated by collapse measures for one, tuberculous bronchial disease for eight, and localized caseous foci for 8; resection incidental to pulmonary decortication following pneumothorax therapy was done in three cases and upper lobe cavitation was the indication for four resections. In the 17 patients, 9 complete lobes, 32 segments, and 8 subsegments or wedges were removed; an average total of four segments, roughly the equivalent of a left upper or lower lobe, was removed in each patient at the two operations. One of the 17 patients died from progressive disease and complications. Two patients were operated on too recently for classification, but have no evidence of active parenchymal tuberculosis. Of the remaining 14 patients, 3 have lesions designated as "inactive" at 6 to 43 months, and in 11 patients the disease is classified as "arrested" 3 to 14 months after the bilateral procedure. At least 10 of these patients would have been considered to have had incurable disease without one or both resections. Bilateral resections in patients with pulmonary tuberculosis became more widely applicable as a result of antimicrobial therapy, which decreases the incidence of complications, and improved surgical techniques that permit resection of sublobar portions of the lung. It is anticipated that bilateral resection will shorten morbidity and provide the only means of cure for large numbers of patients with pulmonary tuberculosis.

Chemotherapy of Miliary and Meningeal Tuberculosis.—The survival rates of 70 patients who received two different regimens of chemotherapy for miliary tuberculosis, tuberculous meningitis, and combined miliary and meningeal tuberculosis with an observation period of at least eight months to more than five years are reported. Of the 70 patients, 44 were started on streptomycin or glucosulfone sodium (Promin) during the first three and one-half years of the study. The remaining 26 patients, in whom treatment was started during the next two and one-quarter years of the study, were given combined therapy with streptomycin and *p*-aminosalicylic acid, and some of them received in addition isoniazid. The survival rate of patients with "pure" miliary tuberculosis was 33.3% in the first group and 83.3% in the second group. The gross survival rate of patients with "pure" tuberculous meningitis was 13.6% in the first group as compared with 69.3% in the second group. The gross survival rate of patients with combined miliary tuberculosis and tuberculous meningitis was 10% in the first group and 71.4% in the second group. Survival rates thus were considerably higher for the second group at comparable periods of observation. It is believed that the prolongation of the original course of treatment with streptomycin from four months to at least one year or more and the addition of *p*-aminosalicylic acid contributed materially to the superior early results in the second group of patients. Since the addition of isoniazid, the results have been even better. The authors

are not convinced that the intrathecal administration of streptomycin is necessary in the treatment of tuberculous meningitis since intrathecal therapy did not appear to favorably influence the survival rates even before the advent of isoniazid. Current results suggest that even better survival rates may be attained providing the "original" course of adequate treatment with streptomycin combined with *p*-aminosalicylic acid and isoniazid is started early, given continuously, and is sufficiently prolonged.

**Study of Role of Adrenocorticotrophic Hormone (ACTH) in Pathogenesis of Tubular Degeneration of Adrenals.* O. M. Wilbur Jr. and A. R. Rich.—p. 321.

Tubular Degeneration of Adrenals.—Wilbur and Rich say that several years ago, one of them directed attention to a peculiar type of adrenal cortical damage that occurs in several acute infections, and pointed out that when the lesion is extensive it is commonly accompanied by peripheral circulatory collapse. The typical Waterhouse-Friderichsen clinical syndrome, particularly when occurring in adults, is often associated with this adrenal lesion in the absence of the extensive adrenal hemorrhage to which the circulatory collapse of that syndrome is ordinarily attributed. The lesion, which was termed "tubular

degeneration" of the adrenal cortex, consists essentially in scattered necroses of single or several cortical cells, shedding of the vacuolated cytoplasm of others, and exudation of fluid from adjacent capillaries into the cortical cell cords, with the resulting conversion of the normally solid cords of cortical cells into tubular structures lined by flattened cells that have lost much of their cytoplasm. The lumens of the "tubules" may appear empty or may contain protein, fibrin, a few polymorphonuclear leukocytes and occasional necrotic cortical cells. The studies presented here aimed to determine whether excessive stimulation of the adrenal cortex by sterile, more purified adrenocorticotrophic hormone could produce the lesion and, if so, what amount of the hormone would be required and how rapidly the lesion could be induced. Adult male Wistar albino rats were the experimental animals. The experiments demonstrated that neither the state of infection nor a direct action of bacterial toxic products on the adrenals is necessary for the development of the lesion. The amount of exogenous corticotropin required to produce the lesion in normal animals under the conditions of these experiments was very large, but reasons are given for believing that, under the conditions of fulminant infection, the pituitary may produce an amount of adrenocorticotrophic hormone sufficient to cause the lesion. The effect of severe tubular degeneration on the blood pressure in the face of infection and the effect of tubular degeneration on the ability to withstand infection and other forms of stress are important questions that can be experimentally investigated by the present method of producing the lesion, and the authors have begun studies directed toward those ends.

Thin Parietal Bones Among the Aged.—A curious flat depression of the posterior horizontal portion of the parietal bones due to localized thinness has been observed in some cases. Epstein recently suggested a relationship between this parietal thinness and postmenopausal, senile, or idiopathic osteoporosis. The present report deals with a roentgenographic study of parietal thinness as it was encountered in a group of 130 aged normal persons, comprising 48 men and 82 women, ranging from 67 to 93 years of age. X-ray examination of the skull was part of a complete roentgenographic skeletal survey of each subject. More than two-thirds of these subjects revealed generalized nutritional osteoporosis, varying from minimal to moderate in degree; several had marked osteoporosis. Five persons, with parietal thinness, an incidence of 3.3%, were

found in this group. All of these subjects had moderate skeletal osteoporosis. This compares with an incidence of 0.001% found by the older anatomists and an incidence of 0.46% found by Camp and Nash after a two year roentgenographic study at the Mayo Clinic. In reviewing the opinions of other anatomists and anthropologists on this subject, the authors say that Greig concluded that parietal thinness was congenital and represented a dysplasia. Some evidence of this possibility was added by Camp and Nash who encountered parietal thinness in the young as well as in the aged. When one considers that the parietal bones are the last to develop and are more subject to changes such as congenital lacunae and trauma, it is not surprising that areas of segmental deploic atrophy with thinning of the parietal bones should occur as variations in ordinary development, simply becoming more prominent in aging atrophic bones.

Treatment of Gout.—Talbott and Lockie call attention to the resurgence of interest in the various articular disorders and evaluate the present status of knowledge on gout with particular emphasis on treatment. They believe that the oral administration of colchicine is the method of choice for the treatment of the acute attack. Phenylbutazone (Butazolidin) and corticotropin may be recommended in selected instances. Colchicine is indicated for each patient periodically in the intercritical period. A powerful uricosuric agent such as probenecid (Benemid) may be used together with colchicine but does not replace it. Avoidance of obesity and restriction of purine-containing foods and fats are desirable. A liberal portion of protein daily is permitted. A high fluid intake is stressed. Prognosis is favorable in most patients.

Prevention of Sodium Retention by Potassium.—Administration of large doses of either corticotropin or the adrenal steroids results in sodium retention that is often accompanied by increased excretion of potassium in the urine and by a decrease in intracellular potassium. In order to minimize potassium depletion, it has become common practice to add supplements of potassium salts to the diets of patients receiving large doses of corticotropin or cortisone. The use of such supplements was also found to be extremely effective in overcoming the sodium retention induced by corticotropin and by

cortisone. The present study was designed to clarify the mechanism of the sodium diuresis that follows the ingestion of large amounts of potassium salts. Experiments were made on 14 subjects: 7 had rheumatoid arthritis, 1 disseminated lupus erythematosus, 1 dermatomyositis, 1 gout, 1 multiple sclerosis, 1 hyperinsulinism, 1 Cushing's syndrome, and 1 no demonstrable disease. In most experiments, potassium salts were administered orally in small divided doses; in a few cases, the potassium salt was given by continuous intravenous infusion. Corticotropin was administered intramuscularly, either in aqueous solution every 6 hours or in 16% gelatin every 24 hours. When either cortisone acetate or hydrocortisone was used, the daily dose was divided into four equal parts administered orally every six hours. It was found that the oral administration of large doses of either potassium chloride or potassium acetate consistently results in a diuresis of sodium. The degree of sodium diuresis is greater in subjects in whom sodium retention has been induced by corticotropin or cortisone than in untreated subjects. The administration of potassium chloride and potassium acetate results in a decrease of urinary phosphate, ammonia, and titratable acid and an increase in urinary bicarbonate and chloride. The increase in urinary sodium is proportionately much greater than the increase in urinary chloride. Two possible mechanisms may account for the natriuretic effect of potassium salts: (1) displacement of body Na^+ by K^+ , and (2) suppression of renal tubular $\text{H}^+ = \text{Na}^+$ exchange. Sodium retention due to therapeutic doses of cortisone or corticotropin can be consistently prevented by the daily administration of 200 mEq. or more of potassium.

Composition of Fibrinoid of Rheumatoid Nodules.—Fibrinoid has been described as a "homogeneous, eosinophilic, refractile, relatively acellular, band-like structure which has some of the tinctorial properties of fibrin." It is found in the connective tissue in the group of "diffuse collagen diseases," including rheumatic fever and rheumatoid arthritis, lupus erythematosus and scleroderma, and periarteritis nodosa. The fibrinoid material of five subcutaneous nodules obtained from patients with rheumatoid arthritis was extracted by treatment of fresh nodule tissue with either dilute sodium hydroxide or trypsin. The extracts of fibrinoid were analyzed for hydroxyproline by a sensitive radioisotope derivative technique and found to contain between none and 0.3 mg. of hydroxyproline per gram of nodule tissue. Collagen content of the nodule tissue ranged between 70.8 and 159 mg. per gram. From the relative areas of collagen and fibrinoid present in microscopic sections of untreated nodules, the approximate concentration of fibrinoid was estimated. Values varied between 17 and 40 mg. per gram. The maximum amounts of collagen that could be present in the extracted fibrinoid, calculated from the hydroxyproline content of the fibrinoid extracts, were found to be about 2% by weight of the fibrinoid. The results indicate that if collagenous material is at all present in the fibrinoid of the subcutaneous nodule, the amounts are negligible.

Radioactive Gold in Treatment of Effusions Due to Cancer.—Simon and associates say that the radioactive gold used at Mount Sinai Hospital in New York City is in the form of a purple-colored radioactive colloidal suspension emitting about 30 mc. per cubic centimeter. The method of introducing the solution into patients is described and explained in a diagram. Radioactive colloidal gold is used in serous effusions to selectively irradiate the lining membrane of the serosal cavity without effecting undue radiation to other portions of the body. On disintegration Au^{198} emits a beta particle of 0.98 mev and gamma rays of 0.12 and 0.41 mev. The beta particles are absorbed in the first millimeter of serosal lining and deliver most of the biologically effective radiation. The gamma rays contribute an insignificant fraction of the radiation dose to the serous membranes, but their high penetration is advantageous, since they can be counted externally when the radioactive preparation is within the patient's body. The authors review observations on 14 patients who were treated with Au^{198} because of pleural effusions secondary to malignant tumors. The administered dose ranged from 25 to 89 mc. The radioactive gold was injected after aspiration of most of the pleural fluid. All patients tolerated the injected gold well. Peripheral blood cell counts were done at frequent intervals in some of the patients, and no leukopenia or thrombocytopenia resulted. Six of the 14 patients had carcinoma of the breast, 4 carcinoma of the lungs, 3 lymphoblastoma, and 1 carcinoma of the fundus of the uterus. Seven of these 14 patients derived benefit from the radioactive colloidal gold treatment. Favorable results were manifested by a decrease in the frequency of chest taps to relieve dyspnea. The histories of three of the patients who responded favorably are briefly presented. The radioactive gold in the circulating blood is less than 0.2% of the dose injected. The gold in the blood is protein-bound to the alpha and beta globulins as demonstrated by filter paper electrophoresis.

Surgery of Saccular Intracranial Aneurysms.—Fifty-six consecutive patients with surgically treated intracranial aneurysms are reported. The over-all surgical mortality was 3.6%, and 7% of the patients had a postoperative hemiplegia. Of 14 patients treated by ligation of the carotid artery in the neck, none died and 1 was rendered hemiplegic. Of 42 patients, 17 who had trapping of the aneurysms between an intracranial clip and ligation on the carotid artery in the neck, 13 who

had trapping of the aneurysm between intracranial clips, 10 who had occlusion of the neck of the aneurysmal sac, and 2 who had packing or reinforcing with muscle or absorbable gelatin sponge (Gelfoam), 2 died (both in the group that had trapping between intracranial clips) and 3 became hemiplegic. The authors feel that a successful program of surgical treatment of intracranial aneurysms depends on careful study of the patient by means of arteriography, with careful selection of patients on whom surgery is to be performed. The following factors were used by the authors in deciding on or against surgery: location of the aneurysm, age of the patient, size of the neck of the aneurysm, the general and neurological condition of the patient, his ability to tolerate carotid compression for 30 minutes (Matas test), and the likelihood of producing an intolerable deficit if it were necessary at operation to sacrifice the artery feeding the aneurysm. The surgeon must decide what is the optimal time for operating during the clinical course of the patient's disease; it must be after the vital and neurological signs of the original attack have leveled off, but before a possible hemorrhage. The danger to life and neurological function is a calculated risk that must be assumed when the decision to operate is made. The outcome of surgery often depends on factors that cannot be forecast or avoided. The surgeon must not only have every detail of the operation planned in advance but be ready for any situation that may present itself. Until he can offer the patient a better chance for improvement with surgery than without, the patient should not be subjected to surgery.

Ligation of Carotid Artery Aneurysms.—Aneurysms of the internal carotid artery, both in the cavernous and cerebral portions, have been treated by proximal arterial ligation in the neck at the Surgery Clinic of the Yale University School of Medicine since 1936. The present series of patients numbers 35, of whom 27 were alive at the time this paper was written. Of the nine patients with aneurysms in the cavernous portion of the internal carotid artery, one died of periarteritis nodosa three years after ligation. Of the 26 whose lesions were in the cerebral portion of the artery, 2 died in connection with the operation, 1 was in a critical condition, and the other was the only patient in the series who had multiple aneurysms. Five patients died after leaving the hospital; two probably of recurrent intracranial bleeding, two apparently of other causes, and one of an unknown cause. The authors feel that their method is reasonably benign and effective in achieving the twofold therapeutic purpose that they envisage—the reduction of strain on the aneurysm with maintenance of adequate circulation to all parts of the brain. While the principle of proximal ligation for intracranial aneurysm is largely on an empirical basis, a study of the stresses operating on the aneurysm—total hydrostatic pressure in the parent artery, the pulsatile nature of the flow, turbulence, and jet action—tends to indicate that the procedure has a sound theoretical basis.

Controlled Hypotension at Intracranial Operations.—The author reports on 60 patients who had controlled hypotension induced by hexamethonium at various intracranial operations. The series comprised 34 women and 26 men operated on at the department of neurosurgery of Serafimerlasarettet, Stockholm, Sweden, between January and November, 1952. The diagnoses in these cases were arterial aneurysm, 28; arteriovenous aneurysm, 4; meningioma, 15; neurinoma, 5; glioma, 3; intracranial metastases, 2; chordoma, 1; Jacksonian epilepsy, 1; and malignant hypertension (hypophysectomy), 1. The postoperative mortality was five patients. Four died from their disease; in only one was the induced hypotension and subsequent treatment contributory to death. Fifty-five patients were discharged after an average hospitalization of 15 days. Four of them underwent reoperation for postoperative hematomas; but there were no other serious postoperative complications. Postoperative shock occurred in no case. The three main indications for controlled hypotension in intracranial surgery are arterial aneurysms, highly vascular tumors and malformations, and rise in intracranial pressure and cerebral edema. Hypertension is generally not a contraindication, since the dangers of a fall in blood pressure of short duration are outweighed by those of rupture of a tumor or aneurysm and hemorrhage. Contraindications are grave cardiac and renal changes, pul-

monary and extrapulmonary processes that considerably impair the oxygen uptake, and shock or impending shock. Hypotensive agents should accordingly be used to preclude bleeding and not be employed as a last resort when the hemorrhage has already substantially reduced the circulating blood volume.

Tuberculous Otitis Media.—The patients whose cases are reviewed by Wallner were seen in consultation during the past five years at two large tuberculosis hospitals. Among a comparatively large number of patients with otitis media, there were 52, in whom there was presumptive evidence of tuberculosis of the ear. Over 200 patients in the same hospital population had the diagnosis of tuberculous laryngitis. The patients seen at these two hospitals were mostly adult men, and all were being treated for pulmonary tuberculosis. The most frequent symptom was aural discharge. Other frequent complaints were tinnitus, a feeling of fullness or blocking of the ear, and defective hearing. The functional tests indicated a conduction type of hearing impairment. The diagnosis of unilateral otosclerosis seemed the most plausible one. The subsequent appearance of inflammatory alterations of the drum membrane, or of discharge, revealed the true nature of the disease. The author says that when he first cared for tuberculous patients, a phthisiologist remarked that any case of discharging ear developing in a person known to have pulmonary tuberculosis could be considered to be tuberculous in origin. This apparently rash statement was confirmed by further experience. The diagnosis of specific infection of the ear depends largely upon the history of painless onset of aural discharge in a person with pulmonary tuberculosis. The otoscopic appearance may not be unusual, and demonstration of acid-fast organisms may be most difficult. The finding of a well-pneumatized mastoid in chronic otitis media may be evidence of tuberculous etiology. The treatment and prognosis of this disease have been completely altered. If seen early, before perforation has occurred, chemotherapy may result in complete resolution of the tuberculous process in the ear. All ear complaints in tuberculous persons, especially tinnitus, a feeling of fullness, or loss of hearing should receive prompt attention. Early diagnosis and chemotherapy may prevent perforation and preserve hearing.

Cortisone Combined with Antimicrobial Agents in Tuberculous Meningitis.—Three adult patients between the ages of 28 and 36 years and four children between the ages of 9 months and 12 years with tuberculous meningitis received combined treatment with cortisone and antimicrobial agents. Treatment was usually begun with 200 to 300 mg. of cortisone daily by mouth when practicable, but intramuscularly when oral administration was not possible. This was usually accompanied by the intramuscular administration of streptomycin or dihydrostreptomycin in doses of 1 gm. daily, and p-aminosalicylic acid orally. In one patient, streptomycin was withheld because of a history of hypersensitivity and was re-

placed by full doses of isoniazid. With the exception of one patient who was given intrathecal injections of streptomycin for a short period, this route of administration was not used. The original dose of cortisone was maintained for every patient until there was decided improvement in the clinical and laboratory findings, and then gradually diminished by decrements of 50, 25, or 10 mg. In all patients a final dose of 5 to 10 mg. daily was continued for varying periods before the drug was finally discontinued. Antimicrobial therapy with one or more drugs was carried on for three to six months after discontinuation of cortisone. Serial x-ray examinations of the chest were made at intervals of two weeks, in view of the known propensity of cortisone to reactivate apparently healed tuberculous lesions. No evidence of the development or reactivation of tuberculous pulmonary disease was noted in any of the patients. Of the seven unselected patients, five recovered and two died. Necropsy was performed in the latter cases and microscopic evidence of regression was noted in the miliary lesions in all organs examined. In one patient, the resolution of an established subarachnoid block occurred in the course of the combined treatment, and, in another, there was evidence that the development of an incipient block was suppressed by cortisone. In one patient clinical and bacteriological relapse, which had occurred after neurosurgical treatment with burr holes, was reversed by the combined treatment with cortisone and antimicrobial agents. Microscopic studies of the tuberculous exudate and other tissues in the two fatal cases revealed a striking lack of cellularity in the tissues and exudates of patients treated with cortisone, as compared with sections from patients treated by conventional methods. It is highly probable that this suppressive action on exudate formation is the prime factor in preventing the sealing off of the strategic foramina at the base of the brain, which frequently may result in irreversible hydrocephalus. The use of cortisone in the presence of active tuberculosis appears to be a safe procedure, provided that it is adequately covered by effective antimicrobial therapy. The importance of early diagnosis and early institution of treatment is again emphasized.

Hemolytic Streptococcus Infection in Childhood.—A four year investigation of hemolytic Streptococcus infection in childhood was undertaken in infants and children attending the pediatric outpatient clinics of the Stanford University Hospitals in San Francisco. Suitable cases of hemolytic Streptococcus infection were discovered in 43 children from 4 to 8 years of age by the application of clinical and bacteriological methods to those who presented symptoms of respiratory infection or by the serial study of 92 infants followed from birth for the first four years of life. In the latter group, infection by the hemolytic Streptococcus was a frequent event, but the disease was usually mild or inapparent. In its severer form it was characterized by the lack of an acute onset, by low grade or absent fever, by rhinorrhea, by a protracted course that was not self-limited, and by the occurrence of frequent suppurative complications. Accurate etiological diagnosis in these patients required bacteriological study of the

nasopharyngeal flora and of the purulent discharges. The administration of penicillin in standard courses, consisting of daily injections of 300,000 units of penicillin in aqueous suspension for five consecutive days or of three doses at 48 hour intervals of the same amount of the drug suspended in oil and 2% aluminum monostearate abruptly terminated the disease process in these cases with prompt and dramatic clinical improvement. After 4 years of age the disease pattern changed so that progressively more of the infections were associated with an acute febrile onset, sore throat, exudative tonsillitis and pharyngitis, and occasionally with a skin rash. Rheumatic fever and lesser manifestations of the rheumatic state occurred after streptococcal infection in children aged over 4 years but were never observed in those less than 4 years of age. Evidence is presented that supports but does not establish the validity of the hypothesis that the changing patterns of clinical response to hemolytic streptococci are the result of repeated infection by these organisms with an alteration in tissue reactivity presumably on an immunologic basis.

Gallstones in Cholelithiasis.—According to Ochsner gallstones represent a real hazard in acute cholelithiasis because of the possibility of the development of dangerous complications such as acute cholecystitis, obstruction of the common duct, choledochitis, intestinal obstruction due to gallstones, acute and chronic pancreatitis, and carcinoma of the gallbladder. This last condition is undoubtedly the most dreaded of all gallstone complications, because once carcinoma has progressed so that it can be suspected or diagnosed clinically, nothing can be done to cure it. Carcinoma of the gallbladder probably never occurs without the presence of gallstones, and, although the risk of developing carcinoma in the presence of gallstones may not be particularly great, possibly between 2 and 5%, the danger of cholecystectomy for uncomplicated cholecystitis and cholelithiasis is much less than this. Only approximately 30% of biliary calculi have sufficient calcium in them to cast a shadow in the plain roentgenogram. In those cases in which there is sufficient function in the gallbladder so that it can be visualized, nonopaque stones are visible as negative shadows. Frequently, however, patients with biliary calculi have severe enough cholelithiasis so that the function of the gallbladder is insufficient to permit visualization. In these instances, the diagnosis of cholelithiasis must be made from the symptoms alone. It is justified in any patient who has recurrent attacks of biliary colic associated with a nonfunctioning gallbladder. If there is any possibility of the presence of calculi, the gallbladder and its calculi should be removed unless there is some definite contraindication, because only in this way can the development of complications, which are responsible for most of the deaths in patients with cholelithiasis, be minimized.

Untoward Gastrointestinal Manifestations Related to Cortisone and Corticotropin.—Sauer and associates present the cases of 10 patients in whom serious untoward gastrointestinal manifestations appeared during or after administration of cortisone or corticotropin. Death occurred in one patient who had chronic ulcerative colitis and in whom perforation of the cecum and peritonitis developed. Perforation of the bowel and peritonitis occurred in two of four patients who had regional enteritis; an enterocutaneous fistula was present in one of these as a result of the perforation. Perforation of an intra-abdominal abscess occurred in a third patient who had this disease. The fourth patient, who had extensive regional enteritis, also had ulcerative esophagitis that either developed during or was aggravated by administration of corticotropin. Complications of peptic ulcer occurred in two patients who had extensive hypercortisonism. One of these patients had massive hemorrhage and ultimately died as the result of adrenal insufficiency after surgical removal of the ulcer. The second patient experienced reactivation of an ulcer and massive hemorrhage; subsequent resection was required. A gastric ulcer that was intractable to medical management appeared in a third patient who had hypercortisonism. Ulcerative rectal lesions developed in three patients; two of them had hypercortisonism and one of these also had a large intractable gastric ulcer. The third patient in this group had proctoscopic findings and clinical symptoms compatible with chronic ulcerative colitis that developed while he was receiving cortisone for treatment of rheumatoid arthritis. Although it is possible that gastrointestinal complications occur in patients receiving cortisone or corticotropin entirely by chance, the evidence from this study and from reports in the literature strongly suggests that administration of these hormones may be a causative factor.

Multiple Duodenal Ulcers in a 9-Year-Old Boy.—The boy whose case is presented was first seen by Robinson in January, 1948, when the history revealed that for the past two years he had had epigastric pains. Examination revealed a rather undernourished youngster. There was tenderness in the epigastrium. Radiographic examination revealed that the duodenal bulb failed to fill properly and to empty completely, leaving two residual pockets of barium in the region of the duodenal bulb. These were interpreted as ulcer niches. The child responded to an ulcer regimen, but in 1949 he returned

with the complaint of epigastric pain and he was again placed on rigid medical care. In 1950, another gastrointestinal series revealed a niche in the duodenal bulb with considerable gastric retention. The pyloric obstruction diminished on a medical regimen as the acute stage of the ulcer subsided. In 1951, the child returned complaining of nausea, vomiting, and loss of weight. Operation was performed in 1952, at which time a subtotal gastrectomy was done. The duodenal ulcer had penetrated into the bed of the pancreas. The ulcer was removed with pancreatic tissue. A pancreatic fistula complicated his convalescence. Subsequent resection of the fistulous tract was followed by uneventful recovery. Robinson feels that, if more children were studied radiographically, a higher incidence of peptic ulcer would be found in children.

Freeze-Dried Arterial Homografts.—The clinical use of arterial homografts has been made practical by the development of storage methods. The types of preservation that have been effective clinically are those that use a quick freezing technique with storage at -80°C , as developed by Hufnagel, and those that utilize a tissue culture-like medium with storage at 1 to 3°C as advocated by Gross. Both methods have several disadvantages. The present report is concerned with the clinical use of arterial homografts preserved by freeze-drying. While processing is somewhat more involved, storage does not require the supervision of specialized personnel; it is not dependent on controlled conditions of temperature, storage medium, and sterility; it is independent of power failure; and the grafts are stored and handled just as a bottle of dry blood plasma and may be shipped by commercial carrier. These grafts have a shelf life in excess of two years. The arterial homografts are obtained at sterile autopsies within 24 hours of death, the body having been refrigerated in the interim. The vessel segments are placed in glass tubes and frozen by immersion in a mixture of absolute alcohol and dry ice at -78°C . After five minutes of freezing in this solution the grafts are either placed directly in a freeze-drying machine or in storage at dry ice temperature to await freeze-drying. For drying, an extensively modified commercial freeze-drying machine is used, and the grafts are placed in a vacuum of 50 to 100 microns of mercury. The temperature is maintained at less than -35°C for several hours. The arterial segments are thus dried by sublimation, the entire process taking about 72 hours. During the last 24 hours, the temperature is raised to 30°C . When drying is completed the residual moisture in the graft has been reduced to less than 1% of the normal unbound water content. The grafts are sealed in bottles under an ionizable vacuum and stored at room temperature. It has been demonstrated in experimental animals that freeze-dried arterial grafts may be used with excellent results. The authors present detailed reports of seven patients in whom 12 freeze-dried vessel segments were used. The patients have been followed for from one to nine months. In all instances patency of the graft apparently has been maintained during this relatively short period of observation.

Diagnostic Value of Tissue Culture Studies of Pleural Effusions.—Sano says that in a previous report it was shown that cells from human body fluids have different growth patterns in tissue culture that may be of diagnostic value. The present paper reports detailed studies of 56 specimens from 50 cases representing varied diseases. These have been grouped more or less arbitrarily into carcinomas, granulomas, lymphomas, and inflammatory conditions. Cellular growth patterns were analyzed, correlated with the pathological states which produced the effusions, and compared with the cell block and Papanicolaou smear studies. The fluids were collected under sterile conditions. If sufficient material was available, 20 cc. of the fluid was used for tissue culture studies and the remainder for cell block study. From one to four hours after removal, the cells were inoculated into two types of medium; one consisting of autogenous plasma (fasting), Tyrode's solutions, and mouse embryo extract, and the other of chicken plasma, Tyrode's solution, and embryo extract. The apparatus was the double coverslip cell of Sano-Smith and the roller tubes of Gey and Lewis. Cinephotomicrography with an inverted microscope and constant temperature chamber permitted the study of the cultures by time lapse moving pictures without interfering with cellular growth. The types of cells, their number, and their behavior were recorded daily for from 3 to 10 days. In situ staining by a procedure applicable to both routine sections and Papanicolaou smears was used to facilitate cellular comparison. With regard to the use of autogenous plasma the author says that in the study of some 400 human tissues it became increasingly apparent that in most instances, though not in all, the cell type and pattern of the original tissue were more closely reproduced in those cultures in which autogenous plasma had been used. The author applies the term kinetic pathology to the culture in vitro of pathologic tissues. In the concluding summary she stresses that the presence of living, multiplying tumor cells has been demonstrated in tissue cultures of pleural effusions in which no tumor cells had been found by any other method. Tissue culture of human effusion cells reflect in most instances the pathologic process active in their donors. Kinetic pathology has been shown to be a valuable diagnostic tool and an adjunct to cell block and smear studies, but not a substitute for these.

Gastrointestinal Ulcerations Complicating Burns.—According to Weigel and his associates, 600 patients with burns have been hospitalized at the Burn Study Section of the Surgical Research Unit, Brooke Army Medical Center, since 1949. Of the 20 patients who died, 5 had proved gastrointestinal ulcerations. In

the first of the five patients, rectal bleeding, occurring on the 10th day after the burn was the first sign of gastrointestinal ulceration. Autopsy revealed four acute ulcers of the intestinal tract, the largest of which was in the posterior aspect of the duodenum and had eroded into the pancreaticoduodenal artery. In retrospect, it appears that surgical intervention to control the hemorrhage should have been carried out when the second hemorrhage occurred. In the second patient, bleeding from the gastrointestinal tract occurred 48 days after the burn. Seven days later the ulcerative lesions in the stomach perforated, and the patient died because of overwhelming peritonitis. In the third patient, the exact cause of death could not be determined, but the large, acute ulcer on the posterior aspect of the duodenum was directly over the pancreaticoduodenal artery. Although this ulcer did not produce any signs or symptoms, it could have caused hemorrhage if the patient had lived longer. The fourth patient had a very extensive burn complicated by acute bacterial endocarditis. Although he died on the sixth day after the burn, acute ulceration of the stomach and duodenum were noted at autopsy. The fifth patient died on the fourth day after being burned. Autopsy findings did not explain the cause of death. Several small ulcerations were seen in the duodenum and ileum, but these lesions did not cause any symptoms. The authors also present pertinent clinical and pathological observations derived from a review of 17 cases of gastrointestinal ulcerations following burns reported in the literature since 1942. Surveying all 22 cases, the authors say that the predominant manifestation of the ulceration was hemorrhage in 10 and perforation in 7; in the 5 other patients, there were no symptoms of gastrointestinal ulceration, the ulcerative lesions being incidental findings at autopsy. Most patients who had ulcerative lesions of the gastrointestinal tract after burns did not show any signs or symptoms of the lesion until hemorrhage or perforation occurred. An emergency operation may be indicated when a massive gastrointestinal hemorrhage occurs after burns.

Duplication of Colon, Bladder, and Urethra.—The boy whose case is presented was referred to the Johns Hopkins Hospital because of a deformity of the penis and because of life-long abdominal distention. From the time the child was 3 or 4 weeks old until the summer of 1948, when he was little more than 4 years old, he never had a bowel movement except with an enema, and he was almost constantly distended. In a series of operations, the first of which was performed in November, 1948, in the belief that the boy had Hirschsprung's disease, (congenital megacolon), complete doubling of the colon, bladder, and urethra was discovered. The entire colonic duplication was removed, the vesical septum was excised, and one urethra was divided. A hydroureter and atrophic kidney were removed. The patient is left with one colon, one kidney, one bladder, and one functioning urethra. He appears entirely well. This type of anomaly, probably representing an incomplete caudal twinning, is to be differentiated from the cystic structures now generally known as duplications and formerly called enteric cysts or enterocystomas. Eighteen other similar cases of true duplication of the colon are reviewed. The mortality of the condition is high, even in the absence of other and graver defects. The duplication generally ends blindly or connects with a small and inadequate fistula. Intestinal obstruction is the chief symptom and requires early relief either by excision of the duplication or by anastomosis of its lower end into the normal rectum or sigmoid. Associated anomalies of the genitourinary tract are extremely common and should be searched for, since operative correction may be required.

Guillain-Barré Syndrome and Poliomyelitis in Newborn.—Two infants, 10 and 8 days old, respectively, born during separate outbreaks of poliomyelitis, presented the Guillain-Barré syndrome apparently associated with poliomyelitis. Guillain-Barré syndrome, hitherto unreported in the newborn, is believed to be caused by a late neurogenic reaction to a variety of different allergens. It has been observed after infections, vaccinations, serum injections, and intoxications. A presumptive diagnosis of poliomyelitis is common in cases of Guillain-Barré syndrome, and the differential diagnosis may be difficult, especially when both conditions are prevalent. Infants with poliomyelitis who are less than 2 weeks old almost always present general flaccidity and tetraplegia, and albuminocytologic dissociation is commonly found in the cerebrospinal fluid. The mother of the first of these patients had typical poliomyelitis, which began on the day of delivery and progressed until both legs, the entire right arm, the abdominal muscles, and the back became paralyzed. Partial recovery followed, but six months later she still had severe paralysis of the dorsal muscles with scoliosis. The child appeared healthy at birth but 10 days later was limp and apathetic. He had no fever, but the paralysis became progressively more extensive until, in addition to the extremities, the abdominal, dorsal, and cervical muscles were involved. Recovery thereafter was fairly rapid, and follow-up when the patient was 2 years old showed no sequelae. It is reasonable to assume that the child's disease was associated with that of his mother in this case, but the manner in which the poliomyelitis virus gave rise to the polyradicular reaction is open to question. Did the boy actually have atypical poliomyelitis, or was his illness merely an unspecific neuroallergic response to the maternal infection? The second child presented an almost identical clinical picture in the beginning, but his recovery was only partial and paralyzes characteristic of poliomyelitis were still present at the age of 8 months. The final diagnosis in this case, in which there was no history of contact with poliomyelitis although an outbreak of the disease was in progress, was Guillain-Barré syndrome following poliomyelitis during the first week of life.

Infectious Hepatitis and Infectious Mononucleosis.—Puncture biopsy of the liver facilitates the differential diagnosis of infectious hepatitis and infectious mononucleosis in their early stages, before regression of the parenchymal lesions characteristic of infectious hepatitis. Both conditions produce similar

mesenchymal changes in the liver, but parenchymal lesions, which are always found in infectious hepatitis, may be slight or even nonexistent in infectious mononucleosis. Histological study of liver specimens obtained by puncture biopsy from 37 patients (14 with epidemic hepatitis, 14 with sporadic hepatitis, most of whom became ill during a period of epidemic, and 9 with infectious mononucleosis) showed both the similarities and the dissimilarities existing between these two viral diseases. Inflammatory histiolympocytic infiltration of the portal spaces and the capillaries, plainly discernible in both conditions, was much more pronounced in infectious mononucleosis, frequently resulting in the formation of inflammatory nodules scattered throughout the lobule. The characteristic parenchymal lesions found in infectious hepatitis consist of necrotic foci, often localized in the center of the lobule, which usually regress completely within 15 or 20 days after the onset of jaundice. Minor differences may still be seen in specimens obtained during the later stages of these diseases, but their diagnostic value is chiefly presumptive, whereas the histological findings of the first 10 or 15 days establish the diagnosis with virtual certainty. The information derived from puncture biopsy is especially useful in atypical forms of infectious hepatitis and infectious mononucleosis in which clinical signs and laboratory tests may be inconclusive.

Cancer of Lung: 100 Years' Statistics.—Grosse states that the autopsy records of the Pathologic Institute of the city hospital in Dresden-Friedrichstadt made it possible to compute statistics on pulmonary cancer over an entire century, that is from 1852 to 1951 inclusive. During this century a total of 78,979 autopsies were performed on adults over 20 years of age, 43,313 on men and 35,666 on women. A total of 10,746 cancers were found, and 1,206 were pulmonary cancers (1,030 in men and 176 in women). The 43,313 men had 5,461 cancers of which 1,030 were pulmonary; and the 35,666 women had 5,303 cancers of which 176 were pulmonary. Since pulmonary cancer is much more frequent in men than in women, the percentage should be computed separately for both sexes, and the over-all percentage of pulmonary cancers should be computed as the arithmetical mean of the percentages for men and for women. The incidence of cancer in general has increased from 1852 to 1951, largely as the result of the progressive increase in the older age groups. Among men the increase in cancer in the course of the century has been from 4.7% to 15.5%, in women from 12.6% to 16.5%. The pulmonary cancers have increased in men from 0.3 to 5.66% of all autopsies or from 6.6% to 35.5% of the total number of cancers in the autopsy material. Since the incidence of cancer in men has increased in the course of the century 3.3 times and the incidence of pulmonary cancer 18 times, the increase in pulmonary cancer was real and not merely due to the increase in the aged groups. Among women the statistics do not indicate a definite increase in pulmonary cancers. The sex ratio of pulmonary cancer shifted in the course of the century from 1:1 to 6.6:1. During the last decade pulmonary cancer has become more frequent than gastric cancer in Dresden. Of 11,591 cases of pulmonary cancer reported in the literature those on the right side predominated over those on the left side in a ratio of 127:100. The pulmonary cancers diagnosed during life have increased since 1930 from 35.5% to 72.8%. Pulmonary cancer is found in all occupations as was indicated in 600 case records, in which the occupation was stated; however, there seemed to be a slightly higher incidence in occupations involving exposure to dusts.

- *Clinical and Histological Changes of Skin Epithelioma After Local Injections of Estrogens. A. Agostini.—p. 397.
Scleroderma and Plasma Protein Alteration. A. Longhi.—p. 435.
Coccarboxylase in Treatment of Herpes Zoster. A. Bottoli.—p. 453.

Local Injection of Estrogens in Skin Epitheliomas.—Water-soluble estrogens (stilbene) injected locally in 21 instances of skin epithelioma produced a clinical improvement, inhibited the development of the neoplasm, and caused it to regress to an earlier stage of its proliferative course. Generally from 12 to 15 injections were given in each case every other day or every two days. A biopsy specimen taken from the center of the ulceration before therapy was compared with another specimen of the same volume and form taken parallel and contiguous to the first after the treatment was discontinued. The connective stroma was improved and the estrogens influenced indirectly the process of reepithelization. The improvement was limited to the epithelium-connective tissue relationships and did not affect the neoplasm itself. There was a marked qualitative modification in the connective tissue but not in the cells of the epithelioma; there were changes in the histopathological substratum with a marked quantitative decrease of cells. The epithelioma never disappeared entirely since the estrogens inhibited the growth of the tumor only. If this inhibiting property will be confirmed by other workers, it will prove that the action of the estrogens does not attack the malignancy in its essence but only influences indirectly some circumscribed sector of the pathogenetic mechanism of the neoplastic development. The main action of the estrogen in these cases consisted in an indirect stimulation of the connective tissue or better of the collagen to hyperplasia. It also influenced the interfibrillary substances with complex biochemical mechanisms. Two factors are noteworthy: the therapeutic efficacy of estrogens on neoplasms other than the sexual ones and the local administration of them. They seem to indicate that (1) the activity of the sexual hormones against cancer is to be attributed to some pharmacological properties independent of their estrogenic property and (2) that the estrogens act on the tissues directly and not through complex mechanisms in which other humoral factors intervene.

*Kerosene Poisoning in Children. P. V. Núñez.—p. 141.
Adenoma of Liver. Case. T. G. Guardia.—p. 153.

Kerosene Poisoning in Children.—People of moderate means in Panama and in certain countries of Central America use kerosene freely as a fuel in kitchen stoves and in lamps. Kerosene poisoning in children is more frequent than believed. It is caused by ingestion of kerosene from containers that are left within the reach of children by careless adults. In the emergency dispensary of the Hospital Santo Tomas of Panama, 382 cases of kerosene poisoning in children were observed from 1941 to 1953. The majority of the victims were between the ages of 1 and 2 years. The quantity of kerosene that the child ingested was not definitely ascertained. The children had medical attention at the dispensary between a few and several hours after the accident. The cases were classified according to the Steiner's classification as follows. The first type includes cases of acute toxicity with depression of the central nervous system, lethargy and sometimes coma, pulmonary symptoms indicating either a minimal or no pulmonary lesion, and quick recovery of the patients within 24 or 48 hours after the accident. The second type includes cases of acute pneumonia, hyperpyrexia and symptoms for several days. The third type includes patients with acute pneumonia and degeneration of the myocardium, the kidney, and the gastrointestinal tract. In the group of patients observed by the author, 242 belonged to the first type, 129 to the second, and 11 to the third. Roentgen examinations were carried out in 123 patients. The bronchopulmonary lesions observed were bronchitis, bilateral pneumonia, pneumonia in the right cardiophrenic angle, basal pneumonia at the right or the left base,

pneumonia at the right upper lobe or at the left middle third of the lung, pleurisy on the left side, and basal pleurisy on the right. The treatment consisted of gastric lavage with a 4% sodium bicarbonate solution, drugs stimulating the nervous system, oxygen, antibiotics, and chemical compounds. The time of hospitalization varied between a minimum of 2 days and a maximum of 26 days for the three different types. Seven patients died. A necropsy was performed in four cases. The lesions found were extensive bilateral pneumonia in one case, toxic punctiform hemorrhagic gastritis in another case, and pneumonia with acute gastritis in two cases. The author urges an educational campaign through the press and the radio to show the people the danger of kerosene poisoning in children and the need of care in preventing the accident.

Carcinoma of Extrahepatic Bile Ducts.—Fleming believes that it is not generally realized that carcinoma of the extrahepatic bile ducts occurs oftener than carcinoma of the gallbladder. He collected from the records of four hospitals in Melbourne, during the 20 year period from 1933 to 1952, inclusive, 130 patients with carcinoma of the extrahepatic bile ducts. Histological proof was available in 102 cases, and these are the basis of this study. There were three distinct patterns of growth: 1. Eighty-six cases showed a diffuse infiltrating growth, involving long sections of duct, in places converting it into a rigid tube resembling a "leather-bottle stomach," but usually with obliteration of the lumen and formation of a bulky, stony, hard mass. 2. In seven cases, a stricture that could be compared with a "ring" carcinoma of the colon was found. 3. In five cases, a fleshy, fungating growth projected into the lumen of the duct with little involvement of the wall or extension beyond it. The macroscopic appearance was not described in four cases. The predominant histological patterns were columnar cell adenocarcinoma, papillary adenocarcinoma, small duct type lined with cuboidal epithelium, spheroidal cell carcinoma, columnar cell carcinoma, and anaplastic carcinoma. There were 51 instances of lymph node metastases and/or distant metastases in other organs. Lymph node metastases involved mostly those around the head of the pancreas, those in the porta hepatis, the cystic gland, and the upper preaortic group. Spread to the liver occurred in 25, to the lung in 10, and to the adrenal glands in 2 cases. The gallbladder was not enlarged in any case of hepatic duct carcinoma and in only 9 of 30 cases of tumor in the triple junction region, but there was an enlarged gallbladder in 28 of 42 carcinomas of the common bile duct and in 10 of the 12 ampullary carcinomas. Gallstones were or had been present in nearly half of the cases, in one-quarter of the male patients and in three-quarters of the female patients. Textbooks state that the onset of this type of carcinoma is that of a progressive, painless jaundice, often preceded by malaise and accompanied by loss of weight. Such a history was elicited from only 38 of the 102 patients. Biliary colic occurred in 18 and pain under the right costal margin or in the epigastrium in the remainder. This pain suggested calculous obstruction of the common bile duct so that the true nature of the lesion was rarely suspected prior to laparotomy. The age of patients with bile duct carcinoma is somewhat higher than that of patients with carcinoma of the gallbladder. The surgical treatment of bile duct tumors is difficult, because the parts are small and the tumors occur in regions where even slight infiltration will involve important structures and make removal difficult. Nearly half of the patients die within the first two weeks after operation.

Laboratory Aspects of Combined Antibiotic Treatment.—The investigations described by Elek and associates are concerned with the lethal action of combinations of antibiotics. The method used consists of a transfer of organisms from the surface of the original medium containing antibiotics to the surface of a fresh medium free from drugs. The transfer is made in much the same way that a rubber stamp transfers ink from a pad to a piece of paper. The stamp consists of a cylindrical block of wood with velvet glued to one surface. Disks (6 mm. in diameter) were cut out of blotting paper with a punch. The concentrations of the antibiotics used were penicillin G, 500 units per milliliter, except for enterococci, when a concentration of 50,000 units per milliliter was used; streptomycin, 1,000 mcg. per milliliter; chloramphenicol, 5,000 mcg. per milliliter; and chlortetracycline (Aureomycin), 12,500 mcg. per milliliter. An agar plate was flooded with a young broth culture that was just faintly turbid and provided the smallest inoculum capable of producing a confluent growth. The test for antagonism was set up as follows. Three equidistant points were chosen on the inoculated plate. The first received a disk saturated evenly with antibiotic A, the second received a disk similarly treated with antibiotic B, while on the third point two similar disks (A and B) were superimposed. Synergism was tested by placing two disks close enough together to produce overlapping of their zones of inhibition. After 18 to 24 hours of incubation at 37 C, the appearances caused by inhibition of growth were noted. A velvet stamp, previously sterilized by autoclaving, was then pressed evenly on the surface of the plate (the "primary" plate) and then pressed similarly on the surface of a sterile plate (the "replica" plate) that was incubated overnight. A total of 65 strains of common pathogens were tested with three pairs of antibiotics—penicillin with chloramphenicol, penicillin with chlortetracycline, and streptomycin with chloramphenicol. The organisms consisted of 28 strains of *Micrococcus* (*Staphylococcus*) *pyogenes* from human lesions, 17 strains of *Bacterium coli* from urinary infections, 10 strains of enterococci from cases of subacute bacterial endocarditis, and 10 strains of hemolytic streptococci. Penicillin with either chloramphenicol or chlortetracycline generally showed antagonism. Streptomycin with chloramphenicol was synergistic. These results refer to interaction after 18 to 24 hours. The only exceptions to these findings were that no interaction occurred.

Perforation of Gastric and Duodenal Ulcers.—Phou and associates review observations on 100 consecutive patients with acute perforated peptic ulcer admitted to their hospital in the four years from August, 1948, to September, 1952. Since 47,500 patients were admitted during this period, the incidence of perforated ulcers was 0.21% of the total and 5.2% of the

1,917 operations for abdominal emergencies. The ages of the patients ranged between 16 and 72 years, but 62, or nearly two-thirds, were between 20 and 40. Although many reports indicate a male to female ratio of 10:1 in perforated peptic ulcers, the 100 cases reviewed here included 17 women, that is, the sex ratio was 4.9:1. There were no decided seasonal fluctuations. A typical history of peptic ulcer was found in 67 of the patients; 21 others had a history of gastric pain and dyspepsia, which, however, was not typical of ulcer; and 12 had no gastric symptoms. The ulcer was located at the duodenal bulb in 54 cases, in the prepyloric region in 34 cases, in the lesser curvature in 10 cases. In two of five conservatively treated patients the exact location was not ascertained. Of the 95 surgically treated patients, 67 were subjected to gastrectomy and 28 to suture. The mortality was not higher with gastrectomy than with suture, and the late results were much better after gastrectomy. Since literature reports likewise indicate the superiority of resection over suture, the authors recommend a wider use of gastrectomy. Listing the indications for either type of intervention, they stress the advisability of gastrectomy particularly for prepyloric or duodenal ulcers, for recurrent perforation, for those with recent hemorrhage, with multiple ulcers, with pyloric stenosis, and for those in whom strict medical treatment has proved ineffective.

Artificial Hibernation in Psychiatry.—A preliminary report is presented from the Department of Nervous Diseases at the University of Munich on the use of Megaphen, a proprietary derivative of phenothiazine, for the therapeutic induction of artificial hibernation in 55 patients with endogenous psychoses (32 with schizophrenia and 23 with cyclothymic conditions) and in 16 patients with vomiting associated with increased intracranial pressure, diabetes insipidus, dazed condition, post-encephalitic obsessive syndrome, delirium tremens, and drug addiction, respectively. Satisfactory results were obtained in one-third of the patients with endogenous psychoses; results were particularly gratifying in manic patients, but chronic patients and those with silent catatonia or retarded depression also showed a good response. Megaphen proved particularly effective in patients with delirium tremens and in drug addicts. The authors caution against ambulatory treatment with Megaphen because of the occurrence of various complications. They feel justified in stating that for many patients the method of chemotherapeutic damping of the disturbed organism seems to be more promising, sparing, and biological than the rough method of electroshock.

Technique of Artificial Hibernation.—Brehmer and Ruckdeschel describe the technique of therapy with Megaphen (a proprietary derivative of phenothiazine), in psychotic patients. In the beginning, patients were given three daily injections of 50 mg. of Megaphen each, and occasionally an additional injection of Atosil, a proprietary preparation of N-(2'-dimethyl-2'-methyl)-ethylphenothiazine hydrochloride. Because of the occurrence of painful infiltration at the area of the injection, 1 cc. of a 1% solution of procaine hydrochloride was added to the Megaphen. Later, the injections of Megaphen were replaced by the oral administration of Megaphen tablets. One tablet contains 25 mg. of Megaphen; the daily dose of the drug varied from three tablets given three times daily to four tablets given five times daily; the latter dose was used in patients with severe motor unrest. Occasionally, particularly in manic patients, in those with alcoholic delirium and during the first days of withdrawal therapy in drug addicts, additional small amounts of barbiturates or meperidine hydrochloride were given. Combined or alternate treatment with pentylenetetrazol shock or electroshock proved possible and occasionally beneficial. Stabilization of the autonomous nervous system was not always obtained with

Megaphen and Atosil; on the contrary, considerable lability was frequently observed in the autonomic nervous system. Tachycardia, gastrointestinal disturbances, and hyperthermia occurred without demonstrable cause. Paralytic ileus occurred in a manic patient. A depressive patient, who had suffered cardiac infarction before the institution of Megaphen therapy, was suspected of having another infarct in the course of this treatment. Fatal pulmonary embolism occurred in a patient who had been stuporous for many weeks preceding Megaphen treatment and who was getting out of bed against advice. Collapse was harmless in patients who were in bed. Mild secondary anemia occurred in several patients after continued treatment with Megaphen for many weeks, but responded rapidly to vitamin B₁₂. Cutaneous allergic manifestations, particularly in female patients, were observed occasionally. Delirium similar to alcoholic delirium occurred in three patients but subsided within a few days after the dose of Megaphen had been reduced. Tremor without delirium occurred in an endogenous-depressive woman after treatment with relatively high doses of Megaphen combined with Atosil for several weeks. Weltmann's coagulation column was mildly increased in this patient, while bilirubin values were normal.

Heparin and the Adrenal Cortex.—The occasional occurrence of thrombosis after operation has stimulated attempts to demonstrate an increased coagulability of the blood in the postoperative period. Crafoord, in the course of an investigation into the prevention of postoperative thrombosis by heparin, noted that heparin had less effect in prolonging the clotting time in the first 48 hours after operation than in normal persons or in the later postoperative period. At Garrett's clinic in Sheffield the coagulability of the blood after operation was investigated in 29 patients by means of a heparin clotting test, and an attempt was made to relate the changes observed to the increased activity of the adrenal cortex occurring as a result of the stress of operation. Statistically significant evidence was produced for a lessening of the effect of heparin on the plasma clotting time in the first 48 hours after operation. Similar effects were shown to occur after insulin coma and electroconvulsion therapy. These changes occur at approximately the same time as the fall in the eosinophil count and are assumed to be due to increased adrenocortical hormone production. Patients receiving corticotropin may show similar changes, and there is a danger that corticotropin and cortisone treatment may be complicated by thrombosis that is resistant to anti-coagulant therapy.

Thrombocytopenic Purpura Due to Drugs.—Bolton and Young point out that toxic purpura occurring in persons who have previously been sensitized by taking drugs often manifests itself in a few hours. Thrombocytopenia that may accompany this type of purpura can also occur in a very short time. If the natural life span of platelets is about five days, then this rapid onset of thrombocytopenia seems to indicate a peripheral destruction of platelets rather than a central failure of production. Some investigators found that a plasma factor was necessary for this agglutination or lysis of platelets. The

authors present the histories of three patients with thrombocytopenic purpura that appeared to be related etiologically to sensitization by quinine, sulfamethazine, and quinidine. The addition of the offending drug to platelet rich plasma from each of these three patients readily caused platelet agglutination and lysis in two and platelet agglutination only in the third.

Antibiotic and Chemotherapeutic Agents in Infantile Diarrhea.—Controlled trials of chlortetracycline (Aureomycin), chloramphenicol, and sulfadiazine in the treatment of infantile diarrhea and vomiting were made at ten separate centers in Great Britain during 1950 to 1952. The trial drugs were administered by mouth in doses of respectively, 75, 75, and 125 mg. per pound of body weight a day for seven days. A total of 1,168 cases (789 mild and 379 severe) was included in the analysis of the results. Infants found to have either *Salmonella* or *Shigella* infections were excluded from this analysis. The numbers in the different treatment groups were 154 treated with chlortetracycline, 415 with chloramphenicol, 247 with sulfadiazine, and 352 controls. The mean fatality rate was 2.8%. Clinical progress after the start of treatment was assessed on the following criteria; average duration of diarrhea, average time to full clinical recovery, and proportion of mild cases that became severe. The group treated with chlortetracycline progressed more favorably than the controls as regards the proportion of mild cases that became severe but not as regards the two other criteria. The groups treated with chloramphenicol and sulfadiazine progressed more favorably than the controls as regards all three criteria. The progress of the group treated with sulfadiazine was significantly better than that of any other treatment group. It is felt that selection of the most appropriate drug for the treatment of individual cases of infantile diarrhea and vomiting may become possible when more is known of the etiology of the disease. The results of the present investigation indicate sulfadiazine and chloramphenicol as the drugs of choice, with the balance of evidence in favor of sulfadiazine. Their oral administration may be considered as a valuable addition to established methods of treatment.

Gastric Aspiration in Hematemesis.—Chandler and Watkinson feel that the early recognition of recurrent hemorrhage and the accurate identification of the site of bleeding in hematemesis and melena are of great clinical importance but are also beset with difficulties. It was thought that in the acute stages of gastroduodenal hemorrhage some abnormality of gastric secretion of diagnostic value might be present. For this reason 24 hour gastric analysis previously used in the study of peptic ulcer and achlorhydria was applied to the problem. The authors report here the results of 24 hour gastric analysis in 105 consecutive and unselected patients admitted, as emergencies, with hematemesis or melena. They found that early hourly gastric aspiration in 105 patients with hematemesis yielded valuable information and proved harmless. The bedside observation of blood staining in the aspirated specimens was useful because further hemorrhage could be detected before other clinical criteria had indicated its presence; its absence sometimes aided localization of the ulcer. A study of the acidity of aspirated specimens revealed that high nocturnal acidity is usual in bleeding chronic duodenal ulcer, that nocturnal neutralization is commoner in bleeding than in uncomplicated gastric ulcer, and that achlorhydria is observed at the time of hemorrhage in acute peptic ulceration, the acid often returning after several days' observation. Achlorhydria in the acute stages of gastrointestinal hemorrhage is thought to be an added indication for continued medical treatment.

New Apparatus for Hypothermia.—The authors designed an apparatus to induce hypothermia and restore body temperature to normal rapidly, since experiments had shown that the survival of animals subjected to hypothermia was in direct proportion to the velocity with which it was induced and withdrawn. The apparatus consists of several units by which and through which water from a reservoir is made to circulate through a two layer rubber suit composed of a hood, a jacket with sleeves (the jacket is made in sections so that either the front or back right or left half of the chest can be left uncovered), and trousers. The suit is put on the patient, and the flow, pressure, temperature, and distribution of the water to its various parts are regulated by a pump, a hydraulic valve, and several special units. The outflow of the water from the suit can also be regulated; as a rule, the authors let it out when it reaches a temperature of 0 C. With this apparatus the refrigerating water, which is obtained from melted ice, is in contact with more than four-fifths of the body surface, and the temperature can be lowered to 25 to 27 C in from 30 to 40 minutes. The initial values can be restored rapidly by sending into the suit hot water that is let out when it reaches a temperature of 60 C. After numerous experiments on guinea pigs and dogs, the authors induced hypothermia in 59 patients with neurological and heart diseases. It was preceded by administration of ganglioplegics (Fargan and Pendiomid). A temperature of from 28 to 32 C was reached in from 30 to 40 minutes with the apparatus, while electrocardiograms were taken every 5 to 10 minutes, and the pulse rate, blood pressure, respiration, and rectal temperature were checked continuously. Oxygen was administered during the operation after which the body temperature was restored to 35 C in about 30 to 40 minutes; at this point the patient regained consciousness and reheating was discontinued. The initial values were reached in from five to six hours. The post-operative course, during which the patients were given a sodium carbonate enema because their acidity had been increased by the intervention, was uneventful. Surgery was performed in 39 patients with congenital malformations of the heart and great vessels; only 1 died of cerebral thrombosis 36 hours after the intervention. The heart had stopped for about 10 minutes in an 11-year-old boy of this group in whom a valvotomy was performed. The circulation was restored by

massaging the heart; the boy made a complete recovery; and there were no cerebral sequelae. Interventions on three patients with acquired malformations of the heart (mitral stenosis) were successful. In one of these a valvotomy was performed under direct vision on a bloodless heart after ligation of the pulmonary artery; the heart was excluded from the circulation for about 4 minutes and 47 seconds. Interventions on patients with involvement of the nervous system (gliomas, meningiomas, angioblastomas, and sarcomas) gave good results in 15. One patient died of coma and one of embolism, 14 and 56 hours, respectively, after the operation. The age of these 59 patients ranged from 3½ to 58 years. These results are very encouraging.

*Erythroblastosis in Triplets. O. Prokop and C. Vollbrand.—p. 452.

Erythroblastosis in Triplets.—Prokop and Vollbrand report the case of a woman who on Nov. 17, 1952, gave birth to triplets, all girls, H., G., and M., weighing 2,250 gm., 3,000 gm. and 3,200 gm., respectively. She had delivered three other children in 1941, 1943 and 1950, and all of these had been free of jaundice or anemia. The two heavier triplets, G. and M., had been icteric since birth, whereas H. had been very pale and only slightly icteric. Within the next few days, the icterus became more pronounced in G. and M., whereas in H. it disappeared, but the pallor increased. When consulted the author suggested erythroblastosis of the newborn in G. and M. and anemia neonatorum in H. The author describes the results of the examinations and the further course of the development of the triplets and says that, as far as he was able to ascertain, erythroblastosis neonatorum has been described in triplets only once before. Other noteworthy aspects were the extremely mild course and the quick response to two blood transfusions in each of the triplets. The fact that the disorder took a somewhat different course in H. than in G. and M. suggested that the triplets were dichorionic rather than monochorionic as had been suspected at first. The dichorionic character was supported by serologic studies that revealed the following formulas: for the father A₁MN P+ccDE; for the mother A₁N P+ccde; for triplets G. and M. A₁N P+ccDE; but for H. A₁MN P+ccDE. The serum of the mother contained three irregular antibodies. That the clinical picture presented by H. differed from that in the other two triplets was explained by the fact that H. had an additional antigen.

*Experiences with Potentiated Anesthesia and Artificial Hibernation. F. Zettler.—p. 1295.

Potentiated Anesthesia and Artificial Hibernation.—According to Zettler, blockade of the autonomous nervous system combined with reduced metabolism exerts a potentiating effect on the hypnotic, narcotic, and analgesic agents. Three grades of functional blockade of the autonomous nervous system combined with anesthesia may be distinguished. 1. The so-called anesthesia premedication, i. e., anesthesia facilitated by the prolonged sedative-analgesic effect of the drugs employed, consists of the oral administration of 0.05 gm. of Atosil (N-[2'-dimethyl-2'-methyl]-ethylphenothiazine hydrochloride) and 0.2 gm. of phenobarbital in tablets on the evening preceding the surgical intervention, and an intramuscular injection of 3 to 6 cc. of a "lytic cocktail" comprised of 0.05 gm. of a proprietary phenothiazine derivative called Megaphen, with 0.05 gm. of Atosil, and 0.1 gm. of meperidine (Dolantin) hydrochloride two hours before the surgical intervention, carried

out with the patient under peridural, local, or nitrous oxide-ether anesthesia. 2. The potentiated anesthesia proper, or partial artificial hibernation, with pronounced stabilization of the autonomous nervous system in the sense of isolation consists of that of the grade 1 anesthesia premedication (6 cc. of the "lytic cocktail" given intramuscularly three hours before the operation) and in addition one hour before the operation a continuous drip infusion (5% dextrose) intravenously or with additional hyaluronidase, of 1 to 2 cc. of the "lytic cocktail" every 15 minutes. The operation then is performed with peridural or local or with general anesthesia with nitrous oxide-ether. Intubation, oxygen, curare, and blood transfusion may be used if required. 3. Artificial total hibernation (a condition of slowed life) consists of the potentiated anesthesia proper (grade 2) with the "lytic cocktail" given three hours before the operation and an infusion with the fractionated "lytic cocktail" and 0.1 to 0.2 gm. of sparteine sulfate two hours before the operation combined with refrigeration performed by means of ice bags one hour before the operation. The "cocktail" is given in 24 hour alternation in the postoperative stage. Additional medication may consist of phenothiazine derivatives, hormones, and vitamins. Potentiated anesthesia of grade 1 and 2 was used in the course of the last three months in 57 patients admitted to the surgical department of the University of Erlangen, Germany. Of the 57 patients, 16 were operated on the brain and spinal cord, 5 on the lungs or esophagus, 27 on gallbladder, stomach, or spleen, and 9 on colon or rectum. Total artificial hibernation was employed in 10 patients subjected to neurosurgical intervention and in 8 patients in purely therapeutic form for ulcerous colitis, endangitis, transverse paresis after accident, and for production of analgesia in inoperable tumors. The usual amount of the anesthetic agent could be reduced to one-third or one-fourth. Nitrous oxide-oxygen may be mixed in the ratio of 1:1 with satisfactory effect. The prolonged sedative effect lasted for about four to eight hours after the operation. Intubation was carried out without any additional medication in one-third of the patients operated on; bronchial or glottic spasms did not occur. The stabilization of the circulation was impressive. There was less lowering of blood pressure than is usually associated with peridural anesthesia. In the course of total artificial hibernation, morphine, hypotensors, and sympathicomimetic agents are contraindicated. Relief of pain was obtained with the potentiated anesthesia. Potentiated anesthesia and artificial hibernation have already become a principle of management by which the limits of surgery can be widened.

*Postvaccinal Meningo-Myelo-Encephalitis. P. Crezée.—p. 3104.

Diagnosis and Treatment of Herniation of Nucleus Pulposus in Lumbar Region. A. Kemp.—p. 3116.

Postvaccinal Meningomyeloencephalitis.—Crezée says that in 1946 and 1947 about 80,000 vaccinations were performed at the military hospital in Utrecht on military personnel to be sent to Indonesia. The majority were primary vaccinations. Among this number, postvaccinal complications of an encephalitic nature were found to develop in 15 and 7 of those patients came under Crezée's observation. One of them died shortly after arrival at the hospital. The histories of the other six patients are presented. Four were 20 years of age, one was 21, and one 23. The disturbances of the central nervous system that were of short duration appeared from 8 to 16 days after primary vaccination. Since two of the patients had myelitis and one an isolated meningitis, the author feels that the more comprehensive term meningomyeloencephalitis is preferable to encephalitis. One of the patients had a relapse of meningoencephalomyelitis two months later. The author was not able to find other reports of recurrences of postvaccinal encephalitis, but there have been reports of recurrences of encephalomyelitis in rubeola. Exogenic contributory factors such as respiratory disturbances were present in several of the patients. One patient had status dysraphicus (faulty closure of the neural tube).

*Tuberculous Meningitis with Reference to Results After Streptomycin Treatment. T. Rasmussen.—p. 1478.

Primary Tuberculosis in Old Persons. E. Eilertsen.—p. 1480.

Treatment and Prognosis in Tuberculous Meningitis.—Of 44 patients with tuberculous meningitis observed for more than eight months after treatment 23, of whom 2 had miliary tuberculosis, were cured. Of the 21 who died, 13 had miliary tuberculosis. All were treated with streptomycin intrathecally and intramuscularly. The last 19 were given *p*-aminosalicylic acid (PAS) from the start of treatment, 3 of them also received isoniazid. Of these patients, 16 recovered; 2 of the 3 who died were extremely ill on admission and had miliary tuberculosis, while in the third streptomycin-resistant tubercle bacilli were present before treatment began. Hauge stresses the importance of starting treatment as soon as possible. The prognosis is best for children over 5, not so good for smaller children and older persons. The results of treatment are less favorable when the meningitis is combined with miliary tuberculosis. Although the prognosis in each case of tuberculous meningitis will always be somewhat uncertain during the first part of the treatment, the results now attained give cause for optimism. Definite clinical improvement should not be counted on until toward the end of the second month of treatment. Examination of the spinal fluid gives indications as to prognosis. The sugar values afford the best evidence of how long intraspinal therapy should be continued; they may become normal in the first month, often in the second or third month. The cell count and especially the protein values will continue to rise for several weeks, presumably because of a special reaction in tuberculous meninges. Such increase is not considered a contraindication for continued intraspinal therapy. The values most often do not become normal till from six to nine months after the introduction of intraspinal treatment.

Tuberculous Meningitis with Reference to Results After Streptomycin Treatment.—From 1931 to 1953, 80 patients with tuberculous meningitis, aged from 6 months to 68 years, were treated in the epidemic department of Odense Hospital. The age distribution showed three peaks—at about 3-4 years, at 14 years, and at 21 years. Up to 1946 the average age was 17.2; since then, 9.5. After the introduction of streptomycin the course of the disease was decisively changed, and for the first time it was possible to cure tuberculous meningitis. The recovery rate was 50% in the 3-14 group, lower in the other age groups. The possibilities for lasting recovery are steadily growing. Prompt treatment is necessary. Complicating tuberculosis elsewhere aggravates the prognosis. Of 16 patients treated with streptomycin, 4 are well after a follow-up for from two to four years, 2 are still undergoing treatment; of the 10 who died, 2 were unconscious on admission. Intramuscular injection has been the standard method, with continuous treatment for the first two or three months, then fractionated treatment. Pauses in the streptomycin treatment, if possible, are advocated because of the side-effects on the eighth cranial nerve, which apparently occur after massive streptomycin treatment. Beginning impairment of hearing seems to disappear on cessation of the streptomycin treatment and recurs on resumed treatment. In the more recent period Rasmussen found it possible to prolong the intervals by the use of isoniazid; by shifting the two preparations the patients were kept free from recurrence and normal temperature was maintained and at the same time side-effects on the hearing were avoided. Peripheral paresis and decreased muscular strength that occur when the temperature is about to become normal are perhaps reasonably attributable to streptomycin side-effects.

- *Treatment of Chronic Obliteration of Superficial Femoral Artery in Arteritis. J. Oudot and J.-M. Cormier.—p. 1512.

Vertebral Angiography.—Radiography of the vertebral artery done percutaneously is a relatively easy technique, although the extreme vasomotor sensitivity of this artery can make its injection difficult. The authors performed 162 vertebral arteriographies in the period from 1949 to July, 1953. They had four major accidents, two of which were fatal. One of the nonfatal accidents was unexplainable; the other three were due to technical mistakes that have been corrected. The authors feel that this method is not dangerous, if the proper indications are followed and the technique well carried out. It should be used as an examination prior to certain neurosurgical interventions. The major indication for vertebral arteriography is a spontaneous meningeal hemorrhage with normal bilateral carotid arteriography. The results achieved in the case of cerebellar tumors are disappointing, but, in tumors of the cerebellopontile angle, the results have been sufficiently good to warrant vertebral arteriography when such a diagnosis is suspected. Deep tumors of the median axis are an indication of choice. In all intracranial tumors, the authors have found that the two most important vascular displacements to be noted are the one in the frontal plane of the terminal bifurcation of the basilar trunk and the one to either side of the distances separating the bifurcation of the basilar trunk from the end-point of the curves made by the two posterior cerebral arteries as they go around the pedicles. Nothing definite can be said about posterior hemispheric neoformations; but it is hoped that, with technical improvements in injection and serial radiograms, many obscure points will be made clear.

Punch Biopsy of Liver in Hepatitis and Mononucleosis.—Punch biopsy of the liver, though not usually necessary in the diagnosis of viral infectious hepatitis or infectious mononucleosis, becomes useful or even indispensable when atypical forms of these diseases are encountered. It is sometimes impossible to differentiate between them clinically, hematologically, or on the basis of functional liver tests and so-called "hepatic serology." The Paul-Bunnell-Davidsohn reaction is more dependable, but not always successful, as demonstrated by the authors' seven cases reported in detail. Punch biopsy appears to be the most reliable deciding factor in the differential diagnosis of these two kinds of hepatitis. It should be done as early as possible, since the lesions are more characteristic in the early stage of the disease.

Obliteration of Superficial Femoral Artery in Arteritis.—Of the various surgical treatments for arterial thrombosis, the one used oftenest by the authors in this series of patients with thrombosis of the superficial femoral artery was vascular grafting. Venous autografts were used in two cases, with mediocre results. Arterial homografts were used for 41 grafts in 35 patients, with the following results: 13 successful of 14 superficial femoral grafts; 4 of 6 femoropopliteal; 2, 1 lasting only 9 months, of 14 iliofemoral grafts; 6 of 6 aortic bifurcation grafts extending to the superficial femoral; and 1 fairly good result among 11 multiple grafts. Endarterectomy alone was done in two cases and occasioned no improvement in the disease. Thirteen lumbar sympathectomies were done; for the five patients for whom it was the only treatment, the benefit was only partial, while in the others, grafting was done subsequently, and results were far superior. Adrenalectomy yielded one good result out of five cases; parathyroidectomy was not performed. The authors state that these methods do not exclude each other but involve different indications. Simple thromboses of the superficial femoral artery ought to be treated

by arterial homografting often combined with a segmental clearing of obstruction. In the case of upward extension, there is no anatomic reason why a graft may not be stretched up as far as the renal arteries; but in the lower region of the leg a necessary requirement to grafting is that one of the chief arteries of the leg be permeable in its initial course. If not, sympathetic operations are indicated, sometimes in combination with bilateral adrenal medullectomy, particularly in younger patients.

Epidemic Asthma.—The term epidemic asthma has been used for the last 30 years to designate epidemics of bronchial asthma caused by allergens contained in certain parasites of cereals or in the dust of the castor bean. The authors report a severe epidemic that occurred in August, 1952, in Bauru, São Paulo. The epidemic involved 150 persons, with nine deaths occurring early in the course of the epidemic. There is in the city a large factory for extraction of castor oil, in which they introduced a new method of extraction of the oil with hexane. None of the patients, both adults and children, worked in the factory, but all of them lived in the city. The epidemic was caused by some allergen in the air derived from the dust of castor bean. The epidemic subsided when it rained. When the day was clear and windy, new cases appeared in districts of the city subjected to the wind from the factory. Some of the patients lived in Agudos, a city 15 km. from Bauru. The symptoms subsided as long as the patients remained in Agudos and reappeared as soon as they returned to Bauru. Some of the patients had the same experience four or five times. Cutaneous tests, passive transfer of the antibodies, and experimental reproduction of asthma were made in 30 patients with positive results. The epidemic subsided when the factory was temporarily closed by the government. It recurred at reopening of the factory and handling of the material with the hexane method. The factory was permanently closed. No new cases were reported. The allergen of the dust of the castor bean is soluble in water and is precipitated in alcohol. For prevention of epidemics, the dust of this and of some of the other seeds used in the oil industry should be kept in containers with water and alcohol, where the allergens will be dissolved and precipitated. The liquid so obtained could be poured into a hole and covered with earth so as to prevent its exposure to the atmosphere.

- Hypotensive Effect of Hydralazine Hydrochloride Combined with Blood Letting. A. Schmid and H. Kellner.—p. 1114.

Hyperglobulinemic Purpura and Sarcoidosis.—Left peripheral facial paralysis occurred suddenly in a 50-year-old woman who for several months had had Waldenström's syndrome of hyperglobulinemic purpura consisting of recurrent purpuric eruptions on the legs, mild normocytic anemia, and hyperglobulinemia with pronounced increase of gamma globulin. There was increased plasma coagulability, but the patient had positive results from the capillary resistance test (employing lacing). The bone marrow showed mild plasmocytosis with definite eosinophilia. Multiple calcified pulmonary and mesenteric lesions were revealed by roentgenologic examination. Within one month, the facial paralysis subsided completely as a result of treatment with vitamins B₁ and C. Six months later the patient had a sudden attack of severe pain in her

left leg. Obstruction of the arteries at the level of the upper third of the calf was observed. Conservative treatment with procaine hydrochloride given intravenously, vasodilators, and ganglion blocking agents failed and so did arteriectomy. Amputation of the extremity was carried out at the lower third of the thigh. The anatomicopathological examination of the amputated specimen revealed thickening of the walls of the popliteal, posterior and anterior tibial arteries with pronounced atheromatosis. The lumens of the vessels were filled with thrombotic masses of hyaline appearance. Microscopic examination revealed interstitial myositis resulting from Besnier-Boeck-Schaumann's disease. It is known that sarcoidosis in its active phase may be associated with hyperglobulinemia, particularly of the gamma globulin, and that this disturbance is to be considered as a reaction of the reticuloendothelial system in the course of sarcoidosis. It was Teilum who demonstrated that the dysproteinemia associated with sarcoidosis favors, in certain areas of the reticuloendothelial system, the occurrence of precipitates of a homogeneous substance passing on to hyalinosis (paramyloidosis). The authors believe that the hyalinosis particularly of the adventitia of the small arteries and arterioles in their patient, as well as the purpura were the results of the hyperglobulinemia. The asymptomatic myositis revealed by microscopic examination made it possible to establish sarcoidosis as the cause of the Waldenstrom's syndrome, and it confirmed Myers and co-workers' suggestion that muscle biopsy may aid in establishing the diagnosis of sarcoidosis in the absence of cutaneous lesions. The occurrence of facial paralysis was reported previously and not unfrequently in association with sarcoidosis. It may be assumed that the pulmonary and mesenteric lesions in the authors' patient were the result of sarcoidosis.

- *Coxsackie Virus and Its Relationship to Bornholm Disease. P. Lépine.—p. 3533.
Bornholm Disease. G. Desse.—p. 3539.
Rheumatic Manifestations of Various Virus Diseases. R. Bastin.—p. 3540.

Coxsackie Virus and Its Relationship to Bornholm Disease.—Coxsackie virus was directly isolated by injecting into infant mice suspensions of feces from 42 patients; in 14 of these patients a clinical diagnosis of pleurodynia (Bornholm disease) had been made; in 16 patients various disturbances of the nervous system, such as nonparalytic poliomyelitis, acute aseptic meningitis, encephalitis, ascending myelitis, were present; and in the remaining 12 patients acute infectious diseases, such as grippe, abdominal syndrome, and acute rheumatism, had been diagnosed. Coxsackie virus, which now has been recognized as the pathogenic agent of epidemic myalgia, is capable of causing in man an infection with protean manifestations of which, as a rule, muscle pain is the present; symptom; the related syndromes depend on the same etiological agent. The physical characteristics of the virus are very similar to those of the poliomyelitis virus; it is one of the smallest of all known viruses. It may be isolated from patients' feces by taking advantage of the fact that infant mice are particularly sensitive to the Coxsackie virus. The infected mice were killed, and microscopic examination revealed changes that were essentially located in the muscle fibers; these changes were characterized by an acidophil hyaline degeneration that terminated in rupture of the fiber. Depending on the individual strain, lesions resulting from infiltration were more or less pronounced. The nerve ends were spared. Microscopic examination of muscle biopsy specimens obtained from patients with Bornholm disease in the course of its acute phase showed changes very similar to those observed in the animals. The Coxsackie virus may be identified by isolation or by serologic methods. There are many serologic types that do not show cross immunity between one another, but three of them prevail and may be commonly observed in France; it may, therefore, be possible to confirm the clinical diagnosis because of the appearance of a deviation of the complement positive for one of the specific antigens.

- *Bronchial Carcinoma: Examination of Material from 1948 to 1952 in Haukeland Hospital. J. R. Myhre.—p. 802.
New Ways of Treating Tetanus. N. Helsingen Jr. and H. P. Østergaard Kristensen.—p. 805.

Bronchial Carcinoma.—From 1948 to 1952, 45 cases of bronchial carcinoma in 29 men and 16 women were treated in the medical department of Haukeland Hospital. Three patients were between the ages of 20 and 40; seven were between 40 and 50; the rest were over 50. Diagnosis was made during life in 38 cases. Information on the first manifestation of the disease was available in 28 cases. The first symptoms appeared an average of eight to nine months before diagnosis was made. Medical advice was sought an average of five months before diagnosis. At least 13 cases were probably inoperable on the first consultation. Surgical treatment was attempted in eight cases; six were inoperable. Pneumonectomy was done in two cases; one patient is well five years after the operation, and the other succumbed to empyema on the affected side a year after operation. Bronchoscopy, usually with biopsy of bronchial mucosa, and planigraphy were the most important aids in diagnosis. A positive histological diagnosis is important in verifying the result of bronchoscopy. Although cough is the most frequent symptom in bronchial carcinoma, it is sometimes absent, even with roentgenologically demonstrated pulmonary infiltration. Vague but troublesome pain in the chest, upper back, and shoulders is often the first symptom and dominates for months. Hemoptyses frequently appear as a scanty mixture of blood and sputum. When pneumonia recurs in the same part of the lung or there is protracted pneumonia, bronchial carcinoma should be suspected. The establishment of hard enlarged lymph nodes in the axillae or supraclavicular region is often decisive. The occurrence of drumstick fingers and hour-glass nails may be helpful in diagnosis; changes in hands and fingers may be the first symptom. Myhre says that in spite of great diagnostic and therapeutic difficulties the prognosis in bronchial carcinoma will improve when physicians always bear the disease in mind, when bronchoscopy, biopsy of the bronchial mucous membrane, and planigraphy are more extensively employed, and when exploratory thoracotomy is applied on wider indications, but even with optimal use of these methods too many patients are inoperable when the physician sees them for the first time. Encouraging results are reported by Hansen and Kjaer from the thoracosurgical department of Øresund Hospital for 1944-1952.

- *Brief Oral Use of Oxytetracycline (Terramycin) in Puerperal Mastitis. A. Heim.—p. 1172.

Oxytetracycline (Terramycin) by Mouth in Puerperal Mastitis.—Heim says that in 1952 he resorted to oral medication with oxytetracycline (Terramycin) in 15 women with puerperal mastitis. In all but one of these women, in whom treatment was begun too late, cure was obtained within a few days without resorting to incision. A total of 8 gm. of oxytetracycline was given in the course of four days. Although the increase in temperature always subsided on the third day, medication was continued on the third and fourth days to prevent a recurrence of the acute inflammation. Except in cases in which painful rhagades were present, breast feeding was continued. Otherwise, the breast pump was used temporarily. The author stresses the importance of the "brief" treatment, only 8 gm. of oxytetracycline being used, whereas in other procedures from 15 to 25 gm. of the drug is given. Treatment must begin as soon as the temperature increases. If abscess formation results despite medication with oxytetracycline, as in the aforementioned case and in patients referred to the clinic with advanced mastitis, incision should be postponed until demarcation of the abscess is evident. This is likewise promoted by oxytetracycline medication. In this case the incision can be relatively small and further extension of the suppurating process to other parts of the breast can be prevented.

BOOK REVIEWS

The Year Book of Drug Therapy (1953-1954 Year Book Series). Edited by Harry Beckman, M.D., Director, Departments of Pharmacology, Marquette University Schools of Medicine and Dentistry, Milwaukee. Cloth. \$6. Pp. 538, with 73 illustrations. Year Book Publishers, Inc., 200 E. Illinois St., Chicago 11, 1954.

This year book covers the literature abstracted from journals received between August, 1952, and August, 1953. All articles abstracted deal with reported developments in therapeutics and are arranged under subdivisions according to the various specialties. One section is restricted to antibiotics and sulfonamides. The editor's introduction highlights the articles of major interest or significance; he also makes specific comments, which appear in brackets after some of the abstracts. His well-known pungent style adds zest to the critical analyses embodied in these comments. Not all authorities will agree with all of them, but for the most part they represent a sound approach to therapeutic problems. The editor cannot be criticized for the failure of authors to use recognized generic terminology for drugs in the titles and text of many of the articles that are abstracted. Undecylenic acid is misspelled as "undecylinic acid," apparently by the authors, in one article abstracted on page 70. There is both an author and subject index. The binding and typography are excellent, and the size is convenient for rapid reading and quick reference. All practicing physicians should find this book a useful review of recent observations on drug therapy.

Treatment of Toxic Goiter with Radioactive Iodine. By Lindon Seed, M.D., Director, Isotope Laboratory, Grant Hospital, Chicago, and Theodore Fields, M.S., Assistant Director, Radioisotope Laboratory, Hines Hospital, Hines, Illinois. Preface by George V. LeRoy, M.D., Associate Dean, Division of Biological Sciences, University of Chicago, Chicago. Publication number 197, American Lecture Series, monograph in American Lectures in Endocrinology. Edited by Willard O. Thompson, M.D., Clinical Professor of Medicine, University of Illinois College of Medicine, Chicago. Cloth. \$3.75. Pp. 116, with 17 illustrations. Charles C Thomas, Publisher, 301-327 E. Lawrence Ave., Springfield, Ill.; Blackwell Scientific Publications, Ltd., 49 Broad St., Oxford, England; Ryerson Press, 299 Queen St., W., Toronto 2B, 1953.

This monograph was written jointly by a surgeon and a radiophysicist and is predicated on their experiences in the treatment of toxic goiter with radioactive iodine. The authors' pessimistic view that the radioisotope laboratory cannot pay its own way is probably incorrect. Recent advances in isotope tracer and therapeutic techniques, including the availability of precisely calibrated solutions and capsules of radioactive material from commercial suppliers, will undoubtedly greatly simplify the problems of purely clinical laboratories. There is a good discussion of the metabolic circuit of radioactive iodine and of its effective half life. This monograph should prove valuable for those who are interested in the mechanics of installing a small isotope laboratory, and it gives in concise fashion the indications for isotope therapy in toxic goiter as well as the results of treatment, including a discussion of such complications as hypothyroidism, exacerbation of symptoms, local reaction, and exophthalmos. These complications are infrequent enough to warrant the authors' prophecy that "the present surgical treatment of exophthalmic goiter will be replaced largely by radioiodine therapy."

Roentgen Diagnosis of the Heart and Great Vessels. By Erich Zdansky, M.D., Professor of Roentgenology, University of Vienna, Vienna. Translated by Linn J. Boyd, M.D., F.A.C.P., Professor and Director of Medicine, New York Medical College, Flower and Fifth Avenue Hospitals, New York. First American edition. Cloth. \$15.50. Pp. 500, with 334 illustrations. Grune & Stratton, Inc., 381 Fourth Ave., New York 16, 1953.

This scholarly treatise has been published in many German editions. The translation is a revision of the last German edition published four years ago. It is a credit to the translator that the book has probably become more readable in the

translation, although the nature and treatment of the subject still makes it a book for study rather than perusal. The serious reader will be rewarded by one of the most thorough analyses of the roentgenographic normal and pathological anatomy of the heart currently available. The sections on the pathological anatomy of the heart are enhanced in value by the excellent treatment of the mechanisms involved in producing the pathological variations. Although some of these explanations may be open to the criticism of being theoretical, the approach is sound. The section on congenital malformations of the heart is small, a reflection of the fact that this book deals predominantly with adult cardiology. As far as the section on congenital malformations goes, however, it gives a working knowledge of the subject without getting too deeply involved in the analysis. The section on the aorta and its pathological alterations is exceptionally good. The book is excellently illustrated with roentgenograms of high quality supplemented by line drawings and colored illustrations. It should be an asset to the library of any cardiologist, radiologist, or internist seriously following the field of roentgenologic diagnosis of the heart and great vessels.

Enriching the Years. New York State Joint Legislative Committee on Problems of the Aging. Legislative document (1953), no 32. Paper. Gratis. Pp. 199, with illustrations. State Senator Thomas C. Desmond, Chairman of the Committee, 94 Broadway, Newburgh, N. Y., 1953.

This pamphlet is one of a series of reports of the New York State Joint Legislative Committee on Problems of the Aging. The committee began its work in 1947 and was the first such group in the country. It has performed a unique and immensely valuable service in behalf of the older persons of New York. Its influence, however, extends far beyond the borders of that state and into every community. The format of this report is unusually good. The booklet is printed on glossy paper in magazine style and has stiff paper covers, an abundance of photographs, a few illustrations, and a number of tables. It is in essence a compendium of 27 essays by leading authorities on various aspects of the problem of aging, preceded by an introduction by Senator Desmond and a chapter on committee recommendations. The essays concern important aspects of the problem: longevity in New York state; food for later years; school days for older persons; training of older persons through correspondence, private trade schools, and other means. The articles are well written and are interesting reading for anyone who has the slightest interest in the problems of aging. With the previously issued committee reports this pamphlet can and will stimulate sympathetic interest in, and a better understanding of, the problems of the senior citizens of our communities.

Anatomy and Surgery of Hernia. By Leo M. Zimmerman, M.D., Professor of Surgery and Co-Chairman of Department of Surgery, Chicago Medical School, and Barry J. Anson, Ph.D., Professor of Anatomy, Northwestern University Medical School, Chicago. Cloth. \$10. Pp. 374, with 204 illustrations. Williams & Wilkins Company, Mount Royal and Guilford Aves., Baltimore 2, 1953.

A distinguished anatomist and a surgeon with an intense interest in hernia have compiled a treatise on the anatomy and surgery of hernia. The superb illustrations and careful anatomic descriptions in the legends will be familiar. The idea that gave rise to the book is sound, and the result is a real contribution to the literature on this subject. Some disjointedness is created by the change in viewpoint from chapter to chapter. Sections on inguinal, femoral, and some pelvic hernias, which make up the major portion of the book, are based on detailed anatomic dissections of the lesions. Other parts are based on more or less accepted normal anatomy and are less authoritative. Moreover, the anatomic descriptions are factual and cold; the description of operations is personal and almost impassioned. It is in this latter area that some differences of opinion may arise, because the surgeon author sets forth al-

most exclusively what he believes, from his experience, to be the proper procedures. Most surgeons today will agree with him that the Bassini operation, which involves suturing of functioning muscle fibers to a semifixed structure, is unsound. There is a curious and interesting use of dissections, in which McVay participated, to elaborate on objections to McVay's using the superior pubic ligament as a fixed structure. On the whole the surgical principles are sound, and controversy will center on details. The authors pay a heartening tribute to H. O. Marcy, whose name is often omitted from discussions of hernia but who antedated Bassini and Halsted by several years. The bibliography, particularly in connection with those chapters that are based on previous publications, is extensive. The book is printed on good paper and is logically arranged.

Roentgen-Diagnostics. Volume III: Thorax. By H. R. Schinz, W. E. Baensch, E. Friedl, and E. Uehlinger. English translation arranged and edited by James T. Case, M.D., D.M.R.E. First American edition (based on fifth German edition). Cloth, \$45. Pp. 2001-3115, with 1084 illustrations. Grune and Stratton, Inc., 381 Fourth Ave., New York 16, 1953.

This book maintains the high standard of the first two volumes of the series. The many excellent roentgenograms help to make this volume one of the most valuable as well as voluminous contributions to roentgenologic diagnosis published in this country. The first 68 pages are devoted to a study of the normal roentgenologic appearance of the lungs. The greater portion of the volume covers thoroughly the diseases involving the thoracic contents, diaphragm, and pleura. The final section covers diseases and malformations of the heart and great vessels. All of the diseases and abnormalities are adequately shown in the illustrations. Line drawings are frequently employed to clarify changes that cannot be clearly demonstrated on the reduced reproduction.

A valuable feature of this work is the extensive bibliography, which covers all of the important and recent work in the field. The book itself is beautifully produced with clear and readable type and excellent cuts. This work has been a vast undertaking, and the publication of the fourth and fifth volumes (completing the series) is eagerly awaited. The translation from the original German is generally excellent, but occasionally sentence structure is so involved that reading is difficult. The retention and use of eponyms, such as Pfeiffer's glandular fever for infectious mononucleosis, will not aid the reader who is unfamiliar with continental terminology.

Metabolic and Toxic Diseases of the Nervous System: Proceedings of the Association, December 12 and 13, 1952. New York, N. Y. Research Publications, Association for Research in Nervous and Mental Disease, volume XXXII. Editors: H. Houston Merritt, M.D., and Clarence C. Hare, M.D. Cloth, \$10. Pp. 604, with 104 illustrations. Williams & Wilkins Company, Mount Royal and Guilford Aves., Baltimore 2, 1953.

Each year the trustees of the Association for Research in Nervous and Mental Disease decide on a subject for the annual meeting. The current volume reports the proceedings of the meeting held in New York in December, 1952. The collected papers cover the relation of the parathyroid, pituitary, thyroid, and thymus glands to various nervous and neuromuscular diseases; the relation of adrenocortical physiology to the nervous system; the effects of high and low environmental temperatures; the role of vitamins, copper, carbohydrates, potassium, lipids, and various enzymes; neurological disorders associated with liver disease; opiate and barbiturate abstinence syndromes; drug psychoses; the physiological development of the cerebral cortex; the relation of porphyrin, creatine, and creatinine metabolism to nervous and neuromuscular diseases; and the effects of inorganic, organic (alcohol), and bacterial toxins on the nervous system. The contributors are all outstanding authorities in their respective fields. Each chapter or group of chapters ends with a discussion and a list of references. One minor criticism is that the discussions appear to have been printed as transcribed, with little or no editing, and hence contain much unnecessary padding. The illustrations are adequate; a list of members of the association is given at the end of the book; and there is an index. Because the papers are highly technical there is little in them that would be of interest to general practitioners, but for those who specialize in neurology, endocrinology, or metabolic diseases the volume is practically indispensable.

The Ergonomics Research Society: Symposium on Fatigue. Edited by W. F. Floyd and A. T. Welford. Cloth, 24s. Pp. 196, with illustrations. H. K. Lewis & Co., Ltd., 136 Gower St., London, W.C.1, 1953.

This book presents a number of contributions dealing with the complex problem of fatigue. It deals especially with anatomic, physiological, and psychological aspects of this problem and the challenge of fatigue to productivity. It has been published under the auspices of the Ergonomics Research Society of England, which was founded in 1949 for the purpose of bringing together anatomists, physiologists, psychologists, engineers, and others interested in the design of machinery and equipment for human use.

A distinguished group of contributors has discussed the subject of fatigue from a wide variety of approaches, including psychological criteria of fatigue; thermal factors in the environment that influence fatigue; tropical fatigue; the effects of fatigue on tremor; some effects of prolonged muscular exertion; the physiological background of fatigue; experiments on positive and negative work; a factor in postponing the onset of fatigue; physiological valuation of work in the Nykroppa Iron Works; muscular potentials as indicators of effort in visual tasks; visual fatigue with special reference to lighting; the fact and fiction of fatigue; motivation in measurements of fatigue; some practical problems of the alertness indicator; work decrement in the learning and retention of motor skills; deterioration of performance on a short-term perceptual-motor task; neglect of the surroundings in relation to fatigue decrement in output; satiation and frustration as determinants of fatigue; and the psychologist's problem in measuring fatigue. The contributing investigators from England, Denmark, Sweden, and the United States represent such fields as psychology, physiology, hygiene, military medicine, ophthalmology, and industrial health.

Certain key statements by various contributors will be of interest. Edholm concludes that "a considerable content of tropical fatigue is psychological rather than physiological," and Ellis states that "in a hot climate the onset of fatigue is facilitated, and the effects are more profound and last longer." Eagles and his associates say that "sleep deprivation leads to a diminution and lessening of fluctuation in tremor. This reflects widespread increasing muscular relaxation." Darcus concludes that it is "possible to improve the methods of work and the design of machines to reduce the effort required and to increase the output attained." Hemingway says "the mean blood flow through a rhythmically contracting muscle may be increased above the resting flow. The blood flow is increased, not during, but actually between the contractions." Asmusen indicates that "at low and moderate velocities of shortening, human muscles can do negative work at a cost of one-third to one-ninth the cost of positive work." Christensen expresses the hope that application of physiological points of view to a rationalization of work might create the best possible conditions for an increased production with a reduced strain on the workmen. Ryan states that "muscular potentials can be used on a statistical basis to reflect the relative effort involved in different tasks, even when the subject is permitted relative freedom of posture and movement." Weston defines visual fatigue as "weariness resulting from the bodily and mental exertion of seeing." Browne says that it is a fact that "prolonged application to a task produces symptoms in the subject and signs in the performance," but "it is fiction that there is a single entity called fatigue." Schwab concludes that "in the investigation of fatigue in the muscles of human beings, one can ordinarily depend upon average motivation levels to give fair examples of muscular performance under different conditions." Gagné questions "the adequacy of the present concept of inhibition in explaining completely the production of decrement in performance during the learning of motor skills." Singleton decided that "deterioration of performance was almost entirely localized in the reaction time component of the skill, the movement time remaining constant." Broadbent concludes that the main preventive of fatigue is "variety in the task stimulus," and Welford says that "disintegration of performance occurs where a 'higher' organization of a task breaks down, leaving the details without coordination or 'drive.'" All physicians and engineers interested in problems of fatigue should find this book of very great interest.

QUERIES AND MINOR NOTES

USE OF TETANUS TOXOID AFTER INJURIES

TO THE EDITOR:—*In this community the question arises as to the use of tetanus toxoid following injuries. Some physicians use the toxoid in place of the tetanus antitoxin. Please give me an opinion on these questions: Following an injury, will the use of toxoid take the place of tetanus antitoxin when toxoid has never been used previously? Will tetanus toxoid take the place of tetanus antitoxin if tetanus toxoid was used more than one year ago?*

E. E. Benoist, M.D., Natchez, Miss.

ANSWER.—1. Tetanus toxoid cannot be used as a substitute for tetanus antitoxin when tetanus toxoid has not been used previously. Toxoid induces active immunity. Depending on the materials and techniques employed, the time of appearance of reliable immunity after tetanus toxoid varies. Nevertheless, a time much longer than the average incubation period of tetanus will be required to induce a state of reliable active immunity. 2. With certain reservations, hereinafter indicated, tetanus toxoid can take the place of tetanus antitoxin when toxoid has been used as long as 10, and possibly more, years previously. The dose required to recall immunity may be small, such as 0.1 ml. of either depot or fluid tetanus toxoid, administered alone or combined with other antigens (diphtheria and/or tetanus), by the subcutaneous or intramuscular routes. As previously indicated, certain circumstances necessitate the combined use of tetanus antitoxin and tetanus toxoid: (a) delay of over 24 hours in the administration of recall doses of toxoid; (b) lesions considered very likely to be associated with tetanus of early onset (short incubation period); (c) marked general debility from any number of causes (bleeding or associated diseases of a debilitating nature), or (d) questionable status of the patient in respect to the previous administration of tetanus toxoid.

SARCOMATOUS CHANGES IN UTERINE FIBROIDS

TO THE EDITOR:—*Is it possible for malignant degeneration to occur in uterine fibroids? What are the indications for surgical treatment in the presence of uterine fibroids?*

M.D., Minnesota.

ANSWER.—It is best to discard the term "malignant degeneration," because a malignant growth is not really degeneration but just the reverse, namely, a growth of new active and destructive tissue. A sarcomatous change in uterine fibromas does occur. In fact it is the most frequent type of sarcoma seen in the uterus. It usually occurs near the center of the fibromyoma. Roughly, a malignant change occurs in about one in 200 fibromyomas. If a sarcomatous change is recognized at operation (every neoplasm should be opened at the operating table), a total hysterectomy and removal of both tubes and ovaries should be carried out. However, there is controversy concerning the treatment in cases in which the diagnosis of sarcomatous change is reported by the pathologist after an operation has been done. There are many gynecologists who do nothing in the belief that the hysterectomy is sufficient treatment. A few resort of irradiation therapy.

Generally speaking, uterine fibromyomas that are not associated with profuse menstrual periods should not be removed unless they are larger than a four months gravid uterus or the patient is infertile and is anxious to have children. In the latter instance myomectomy should be performed. Rapid growth of fibromyomas is another indication for surgery, because it may indicate malignant change. Fibromyomas larger than 10 cm. found in women who have been in the post-

menopausal period for at least two years should be removed because in nearly all instances simple fibromyomas decrease considerably in size after cessation of menstruation. Since there is only about one chance in 200 of a malignant change in fibromyomas and since these malignancies are apparently not as serious as sarcomas of the uterine muscle and uterine endometrium and blood vessels, it is not justifiable to remove all uterine fibromyomas.

SMALLPOX VACCINATION

TO THE EDITOR:—*A 3-year-old boy has been vaccinated 10 times for smallpox without a "take." Three different vaccines have been used, with all of which there have been "takes" on other children. Do you have any suggestions? I have heard of two persons who failed to have a smallpox "take" and some years later contracted smallpox.*

John A. Putnam, M.D., Carthage, Mo.

ANSWER.—As a general rule, it has been stated that the absence of a reaction to vaccine does not indicate immunity. It indicates oftener either that the vaccination was not properly performed or that the vaccine was not potent. Many physicians adopt the policy of attempting the revaccination at about three month intervals until a "take" is obtained.

NEUROSURGERY IN MULTIPLE SCLEROSIS

TO THE EDITOR:—*A 39-year-old man with moderately advanced multiple sclerosis has a scissor type of gait. He is confined to his wheel chair most of the time and whenever he attempts to walk he has a cross-legged gait. He has bilateral ankle clonus and a bilateral Babinski reflex. Clonic spasms occur during sleep in both legs, and, when he awakens in the morning, he complains of pain in the adductor group of muscles of each thigh. A neurosurgeon has suggested that the patient submit to bilateral section of the obturator nerve as a means of relieving the rigidity of the adductors. Is this a recognized procedure, and, if so, what are its disadvantages? The patient has received large doses of mephenesin (Tolserol) without benefit. I believe that, because he has so much spasticity of all the leg muscles, section of the obturator nerves would be of little help in permitting him to get along on crutches.*

M.D., Minnesota.

ANSWER.—Section of the obturator nerve is a well-established procedure that aids patients with paraplegia to walk by preventing the crossing of the legs. It is a minor operation and quite justifiable in such a patient.

TESTICULAR BIOPSY

TO THE EDITOR:—*Is it considered definitely proved that testicular biopsy is absolutely free of any danger, especially as far as the development of testicular tumors is concerned in a cryptorchid person?* H. Hinglais, M.D., Paris, France.

ANSWER.—Testicular biopsy is an innocuous procedure, devoid of any important complications either immediate or delayed. The most serious immediate complication is hematocoele, which can be avoided by careful selection of a bloodless area for incising the tunica albuginea. Postoperative pain is negligible if the tunica albuginea is not sutured. In over 2,000 biopsies, only two hematoceles resulted and these occurred in the first 100 cases. No reports have appeared on delayed complications. Operative exposure of the testis either months or years following biopsy reveals either no evidence of the former incision or an insignificant scar. In the performance of serial biopsies, tissue removed from the same spot as the previous biopsy (if that can be located) reveals no evidence of trauma. In cryptorchidism, biopsies are performed during

the course of orchidopexy. Thus far, 57 biopsies have been performed on immature testes that were exposed for orchidopexy, and 130 biopsies have subsequently been done on the same testes in order to observe their later development. The literature contains no report of malignancy nor is there known to be a single instance of unreported malignancy.

INJECTIONS OF BEE VENOM FOR ARTHRITIS

TO THE EDITOR:—A patient whom I was treating for tear duct stenosis up to 1945 was interested in bees. He was stung every once in a while and during this time never had one ache or pain of arthritis. He then moved to Wisconsin and recently began having arthritic pain. He asked a physician to inject the venom of bees, and after a few injections he was free from any rheumatic condition. As I have never heard of this therapy for arthritis, I would like your opinion.

C. Messmer, M.D., Milwaukee.

ANSWER:—Bee stings and injections of bee venom have been used in various rheumatic disorders for many years. The results, at best, can be said to have been only equivocal. A review of the literature in English since 1936 reveals that some physicians as recently as, but not since, 1942 have advocated the injection of bee venom for rheumatoid arthritis. However, other investigators found that similar results were obtained when solutions of magnesium sulfate, glucose, or foreign-protein material were injected or when physical therapy alone was employed. Most of the publications by those who favor the use of bee venom in rheumatoid arthritis merit the criticism of Kroner and associates (*Ann. Int. Med.* 11:1077-1083 [Jan.] 1938), who stated: "However, in spite of the many articles that have appeared on the use of bee venom for the treatment of rheumatism there is hardly one that presents evidence of a scientific application of this form of therapy. In most instances, the type of rheumatic disease studied is not clearly defined, the number of patients treated is small, and only generalized statements regarding the results are given." Bee venom does not appear to have any specific curative effect in rheumatoid arthritis; it is doubtful that it has any significant antirheumatic effect other than that which occasionally is seen temporarily following the injection of many irritating substances.

CAUSE OF AMENORRHEA DURING LACTATION

TO THE EDITOR:—What is the physiological basis for the amenorrhea present during lactation? M.D., Louisiana.

ANSWER:—There is still some uncertainty as to the cause of the amenorrhea that may be present during lactation. The immediate factor is rather generally accepted to be the suppression of the pituitary gonadotropin. This inhibition probably comes from the pituitary lactogenic hormone, since no evidence has ever been adduced to support the older hypothesis that the lactating breast produces a hormone responsible for inhibition of ovarian function. It is now well established that menstruation reasserts itself at varying periods after parturition, even if lactation is continued; and that the earlier cycles are often anovulatory, as shown by a number of authors (Topkins, P.: *Am. J. Obst. & Gynec.* 45:48, 1943; Lass, P. M.; Smelser, J., and Kurzrok, R.: *Endocrinology* 23:39, 1938).

RADIATION FROM HIGH TENSION WIRE

TO THE EDITOR:—Is there any evidence that radiation of electricity from a very high tension wire could cause impairment of health of those exposed to it?

John T. Bate, M.D., Louisville, Ky.

ANSWER:—There is no evidence that electromagnetic radiation from a high tension wire could, under any ordinary conditions, cause impairment of health of those exposed to them, unless, of course, a person came in direct contact with the wire so that current flowed through his body to the ground or to some other object of a different electrical potential. The electromagnetic waves from high tension wires could have only the production of heat as their chief effect on the human subject. The field strength is so low that it is doubtful that any perceptible heating of body tissues would occur.

USE OF OXYTOCICS

TO THE EDITOR:—Kindly advise as to the current consensus of use of oxytocics, first in normal vaginal delivery and second in cesarean section.

R. E. Mailliard, M.D., Storm Lake, Iowa

ANSWER:—The majority of obstetricians today use oxytocics in both vaginal deliveries and cesarean sections. The difference of opinion is mainly over the proper time to use them. It has been shown over the years that the use of oxytocics saves blood. Some use pituitary products (preferably those low in pressor activity) with the delivery of the head, believing that the placenta separates quickly and that the uterus therefore contracts down better, saving blood. With this method the placenta usually follows the delivery of the baby by one to two minutes. Others will not give any oxytocics until after the delivery of the placenta but at this point give either the pituitary or ergot type of drug or both. Probably the majority of obstetricians give ergot preparations for from one to three days following delivery.

There is apparently some danger in giving pituitary products while cyclopropane is being used as an anesthetic, and also some cases of so-called allergic reactions have apparently occurred even in the absence of anesthesia.

TREATMENT OF VENEREAL WARTS

TO THE EDITOR:—In the Aug. 15, 1953, *JOURNAL*, page 1581, was a comment on venereal warts that recommended that podophyllin resin, a dusting powder of thymol iodide, or potassium permanganate in dilute solution be used.

In THE *JOURNAL* of July 11, 1942, page 874, was a report under the heading of "Radium Therapy for Vulvar Condylomas." These lesions on women have been quite successfully treated with small doses of radium by local application. It was felt that radium irradiation was more limited and localized than x-irradiation. It was shown that 100 mg. hours of radium should be sufficient for a 4 sq. cm. area. It was suggested that smaller doses be used initially and applications repeated if necessary. This suggestion is added since the use of x-ray and radium irradiation was omitted in the answer. Admittedly these comments are offered only from the viewpoint of an obstetrician and gynecologist.

University of Chicago

5841 Maryland Ave., Chicago 37.

IRRITABLE BOWEL SYNDROME

TO THE EDITOR:—The query on "Irritable Bowel Syndrome" in THE *JOURNAL*, Aug. 15, 1953, page 1585, was of interest to me. It might be useful to the questioner to consider that intestinal symptoms can be caused not only by food but by irritating substances that enter by the respiratory route. As an illustration, an older woman had very bizarre intestinal symptoms; a diagnosis of psychoneurosis had been made, but the symptoms were proved to be caused by her use of a down pillow. When all the feathers were discarded, there were no more symptoms. Somewhat similarly, she had a much milder reaction to bed linen that was laundered at a public laundry. The use of detergents instead of soap can apparently contribute to such symptoms.

A. E. Taft, M.D.
Haverford, Pa.

UNEXPLAINED SWELLINGS

TO THE EDITOR:—The case described by the consultant in answer to the query on "Unexplained Swellings" in the Oct. 17, 1953, issue of THE *JOURNAL* bears a striking resemblance to one in which I was consulted several years back. This case proved puzzling until it was suspected, and later proved, that the edema was self-induced by use of a ligature.

ORGANIZATION OF THE DEPARTMENT OF SURGICAL PATHOLOGY

Edwin F. Hirsch, M.D., Chicago

Forty years ago, if the conditions prevailing in Chicago are taken as representative of those in other large medical centers, the practice of surgical pathology did not exist. A few of the tissues removed by surgeons were taken to the pathology departments of medical schools and the professor of pathology was approached with the statement that here was something of unusual interest. Had he suggested a small fee for this service, the professor would have been regarded as ungrateful of a privilege. He, of course, was most interested in pathological material obtained through his own necropsy examinations, and he had little concern for the tissues that the surgeon removed. Later, the surgeon himself, realizing that much and sometimes significant diagnostic information was obtained by the microscopic examination of a surgically removed tissue, organized a small laboratory for preparing tissue sections. He or his assistants interpreted these preparations. Next, laboratories in hospitals took over this function and pathologists were employed to supervise the clinical laboratories, examine the tissues removed at surgery, and make the postmortem examinations.

If 1922 is chosen as the beginning of the second decade of the last 40 year span, in that year the laboratory at St. Luke's Hospital examined 1,137 tissues removed at surgery and 1,272 tonsils. At that time the examination by the laboratory of all tissues removed surgically had been a routine practice for several years. These figures indicate that 52.3% of the surgical operations in that year were tonsillectomies. For the year 1932, the beginning of the third decade, the number of tissues removed at surgery was 2,667 and of tonsils 1,282. The tonsillectomies accordingly constituted 32.5% of the total surgical operations. The totals for 1942 were, respectively, 4,813 and 637, and the percentage of the tonsillectomies had decreased to 11.6% of the total surgery; and in 1952 these surgical procedures numbered 7,189 and 251, with the number of tonsillectomies only 3.3% of the total surgery. The increase in the number of tissue examinations in each of the last two decades does not result from the broader application of a routine practice but reflects the greater utilization of biopsy examinations in diag-

nosis, especially in the field of cancer, and also the development of specialized practices in surgery, notably bronchology.

LABORATORY PROCEDURE

The processing of tissues is the duty, of course, of only one of the departments of a clinical laboratory. The segregation of this work from that of other departments, especially when many tissues are examined, reduces distraction and the attendant chances of error. Any system to preserve the identity of a tissue removed at surgery for examination begins in the operating room. Large tissues are wrapped in wax paper and then a requisition is fastened, giving the patient's name, the bed location, the date, the attending physician, and other pertinent data. Small particles or pieces of tissue go directly into a glass container with a fixing solution, preferably Zenker's solution with acetic acid, also suitably identified. The operating room personnel sends to the laboratory, the tissues and a large ledger book in which are entered, according to date, the name of the patient, the tissue, and the surgeon. The tissue technician in the laboratory signs and records in the proper column in the book the time of arrival of each tissue.

Tissues arriving during the day are collected in a refrigerator or other suitable place and at a scheduled hour, preferably late in the afternoon, the pathologist makes the gross examinations and selects the portions of tissues to be fixed for sections. Each requisition is numbered consecutively during a year, beginning with the first day of January and ending Dec. 31. The tissue and its record then receive a number of a year. A small piece of paper with the proper number marked in pencil is placed with the tissues being fixed in a container. This slip is transferred with the tissues as they pass through the various solutions for dehydration, clearing, and paraffin infiltration.

Pressure for the prompt diagnosis of a tissue obtained at biopsy confronts every pathologist. A small piece of tissue can be processed readily in 24 hours or less. When many small biopsy specimens requiring 24 hour diagnostic service come to the laboratory, the pathologist has a larger problem, the processing of the large blocks of

tissue that require more time and the processing of the small pieces within a 24 hour schedule. My comments concern chiefly the second group, because these tissues need a special technical procedure. Moreover, the method herein described can be used for the cytological examination of various fluids.

METHODS OF PROCESSING TISSUES

Tissues for sectioning are processed usually by transfer from one liquid into another with instruments or a mechanical device. Besides the "forceps-pick-up" method for moving the small pieces, various carrying devices have been proposed, such as collecting the particles on filter paper, lens paper, or gauze and then passing the gauze or paper through the reagents. A special metal centrifuge tube with a screw-out tip for collecting small particles of tissues has been described. A simple method devised in the laboratory at St. Luke's Hospital to process and to conserve the small biopsy specimens uses the principle of centrifugation, bringing the reagents to the tissues rather than the tissues to the reagents. It is advantageous in biopsies of bronchial tissues and aspirations, with fluids of all kinds, and for the cytological examination of cervical and uterine fluids or tissues.

Ordinary 15 ml. centrifuge tubes of good quality glass with a cork or rubber stopper, or, if required, cotton stoppered and sterilized, are used. The small tissues removed by the surgeon or bronchologist are transferred directly into such a tube. A small amount of isotonic sodium chloride solution can be placed in the tube to help release the tissues from the jaws of the instrument used to remove them at biopsy. Zenker's solution is then added, the tube is stoppered, and an adhesive strip bearing the patient's name is fastened to the outside. The bronchologist at St. Luke's Hospital, Dr. Paul Holinger, has had his bronchoscopy instruments constructed so that a centrifuge tube for collecting fluids by bronchial aspiration can be attached directly to the instrument. Zenker's solution is then added, the tube is stoppered, labeled, and sent to the laboratory. Fluids of all kinds are processed in this way. Those with sediments are centrifuged before fixation, and the sediment is then fixed; those without sediment are precipitated by adding Zenker's solution. With a small curet, superficial tissues of the cervix, the cervical canal, or pools of vaginal fluids are removed or collected, transferred to a centrifuge tube, and then fixed in Zenker's solution. The processing of these tissues in the laboratory is continued by centrifuging, decanting reagent fluids, and adding new ones. After dehydration with alcohol, toluene or xylene or other suitable reagent is used for clearing and, finally, melted paraffin is added and the tube is placed in the paraffin oven. The paraffin can be changed as required. When the tube with paraffin is removed finally from the incubator, a copper wire loop is hung over the lip of the tube so that it dips into the liquid paraffin. After the paraffin is solid, the tube is gently warmed in water and the entire paraffin mass, molded to the shape of the tube, lifts out with a slight pull on the copper wire. The tip portion containing the tissues or cells for examination is cut off horizontally

and embedded in a small amount of melted paraffin. This block containing the tissues or sediments is cut with a rotary microtome and ribbons of sections are mounted and stained. By this method all small biopsy specimens are sectioned; the procedure has met in hospital practice the requirements of cytological studies of all kinds of fluids and secretions. A method of this kind has the advantages of concentration instead of dispersion of microscopic materials; it enables the pathologist himself to make a large number of cytological examinations in instances in which screening by the smear and oil immersion examination method would require a trained technician; it permits the application by the pathologist of his experience and training to the evaluation of all cell masses found rather than to toss away these standards for a method that acceptedly is a screening procedure; and the pathologist also has a chance to recognize tissue lesions other than those cancerous.

Tissues removed at surgery after gross examination and description can be preserved in deep-freeze units and in preserving fluids. There are limits of time and space to these procedures. The paraffin blocks of tissue can be stored for many years in space outside of the laboratory. Prepared slides are filed according to number and year in cabinets bought or constructed for this purpose.

LABORATORY RECORDS

The final report to the clinical record and to the attending physician generally is more than a diagnosis. It should include adequate gross and histological descriptions as well as the pathological diagnosis. Chief problem of the pathologist is not handling the copies that leave the laboratory but rather devising a system for keeping the original copies accessible and in order. Loose filing cards are unsatisfactory. During my years at St. Luke's Hospital I have used a sheet of good quality paper, 9½ in. by 8½ in., on which is printed items such as name, date, attending physician, room or ward number, and diagnosis and a blank sheet that is used for descriptions longer than those that can be typed on both sides of the first sheet; blank sheets are also used for mounting sketches, drawings, photographs, photomicrographs, and other addenda in a record. Any other size of paper sheets or printed items can be used; the size mentioned is satisfactory for current filing purposes in a vertical file according to number and later for binding into books. The tissue reports are typed with carbon copies on regular typewriting paper. The original copy is retained for the record files in the laboratory, a copy is added to the patient's clinical record, and another is sent to the attending physician. A temporary index of patients' names, with assigned tissue numbers, is made on small sheets of paper and alphabetically arranged in an index file. These slips placed in alphabetic sequence are used later to type the permanent name index of each volume of tissue reports. Six hundred surgical tissue reports with included sketches, photographs, and photomicrographs form a bulk convenient to bind into a volume. Each volume has an alphabetically arranged index of the names of patients, with assigned tissue numbers, and a simple, cross-

indexed, alphabetically arranged list of diagnoses reported in the volume. With practice these indexes are prepared quickly.

USE OF PHOTOGRAPHY

Photography has been used in many fields of medicine and is especially useful in pathological anatomy. Photographs in black and white or in color can serve several purposes: (1) to supplement a tissue report or a necropsy record; (2) to illustrate lesions in discussion with student, intern, resident, and attending staff groups; (3) to collect, file, and display in a photographic museum of pathology; (4) to organize into exhibits for hospital corridors and elsewhere; and (5) to provide illustrations for publications or texts. A photograph approximates the appearance of a tissue, the black and white medium expressing this in shades of the dark and the light and the colored picture by contrasts of color. A better result is sometimes obtained with the shades of gray and sometimes with the colors. The preparation of a tissue for photographic purposes is the first important step. No photographer can reproduce in a photograph more than the tissue contains. It must be opened or cut to expose clearly the lesion or structures to be photographed. The knives and other instruments used must be sharp to make smooth surfaces. After the results had been disappointing in photographing unfixed tissues, tissues immersed in water and photographed through glass, the more reliable and satisfactory procedure of tissue fixation with solutions for preserving color was adopted at St. Luke's Hospital. The elimination of high lights and the reproduction of details and color are important. Prompt fixation of the tissues in fluids for preserving their color after suitable preparation of the lesion accomplishes this. Tissues carried through the Kaiserling solutions no. 1 and no. 2 or Jores solution no. 1 are suitable for photographing in black and white or in color. A box built with an illuminated blue-green background and with corner supports for a clear plate of glass placed at a higher level and on which the tissues are photographed is required. Skill and experience in the art of photography are as essential in tissue photography as they are with other subject material. Doubtless the preservation of gross tissues in museum jars for teaching purposes will continue but not in the volume that prevailed before the present level of photographic achievement was reached. Photographs offer many advantages and uses over the preserved specimens.

PRESENTATION OF STAFF CONFERENCES

Pathologists in hospitals are expected to present clinical-pathological conferences for the attendant and resident staff. The attendance at these conferences and the interest displayed in them are determined by the quality of material offered. Needless to say, many specialists in the various branches of medical practice have been trained in centers in which these conferences have been conducted at high levels. They expect the same high quality from the pathologist who serves the hospital in which they practice. The pathological material presented in these conferences is not offered to one individual or several but rather to large groups. For effective demon-

stration the use of screen projection is required. Printed and typewritten material, photographs, and transparencies can be projected onto a large screen with opaque object and lantern slide projectors. Photographs mounted on 8½ in. by 10 in. cards can be collected according to systems in files and indexed. The black and white and color transparencies for projection purposes are also filed and indexed. These collections and the files of tissue reports and necropsy records, all in a numerical system, become a museum of pathology. Sets of histological preparations, as unknowns or with indexes arranged according to the specialties and with the same system of numbering, provide training material in pathological histology. Reports of tissues removed at surgery or necropsy records are available for consultation.

With these arrangements and the practice of keeping paraffin blocks of surgical and necropsy specimens in storage indefinitely and the Zenker-fixed and formaldehyde-fixed necropsy material for a reasonable time, the hospital pathologist is able to meet practically all of the demands of his tissue work.

PROBLEMS IN TISSUE DIAGNOSIS

Every pathologist practicing his specialty in whatever circumstance is confronted with problems in tissue diagnosis. What is the tissue lesion? Is it inflammatory or is it neoplastic? No one has a mystic ball out of which he may conjure up the answer, and I do not believe that any pathologist has a God-given talent for tissue diagnosis beyond the characteristics of ability to observe details and to interpret their significance. Training the eyes to see and the mind to think are the important ingredients in this work. The final diagnosis of a tissue examination has the elements of gross features and microscopic details, either one dominant or both of relatively equal value. Gross features unless changed by handling, desiccation, or autolysis remain constant. The choice of tissues for microscopic examination, however, and the final product in the sections are variables. Choice of material or the sampling must be adequate. The one technical defect that seems to me the greatest handicap to pathologists in tissue diagnosis and for which the pathologist himself is responsible is the poor quality of his histological preparations. Every athlete trims his load to the minimum and seeks out the greatest advantages for demonstrating his skill in competition. Why should the pathologist do otherwise? The quality of the final section is determined by tissue fixation, the kind of fixative and the time the tissues are fixed, the care of embedding, the precision in sectioning and in the mounting of sections, and staining. How many of us can give constructive suggestions to a tissue technician on the basis of actual personal training and experience? Who realizes in tissue diagnosis that a whole battery of different stains, many of them more specifically designed for the stroma of tissues than for epithelium, affords little more diagnostic information than confirmation of a good histological preparation stained well with the simple hematoxylin and eosin stains? I am also one of those who think that a pathologist to be skillful in diagnosis must continually

check his observations and conclusions, so far as is possible, by the patient's progress and especially by necropsy examinations. Who among us has the zeal and interest to follow outside of his laboratory—in the hospital, across the street, across the city, to another city, or halfway across the continent—a controversial tissue diagnosis and learn by necropsy the validity or falseness of his conclusions. The discipline can be comforting as well as confirming; it can be starkly revealing and teach an unforgettable lesson. Both of these can be of great benefit to the pathologist. Good principles of practice apply in surgical pathology just as they do in the other specialties of medicine.

Among the sharpest critics of pathologists are his professional associates. He serves them as well as the patients. When the results of a tissue examination agree with the clinician's opinion of the disorder, there is no difficulty. With disagreement, there can be difficulty, and under these circumstances emotional factors enter. These personal relations have many aspects and to reduce their solution to a single formula is not possible because the tension of the emotional factor on either or both sides can be small or it may reach the "explosion" level. I have only suggestions to offer: 1. Try to keep the discussion and thinking at the adult level; a simple reasonable question helps to get the discussion into this channel. 2. Silence is often golden; a good listener can release a lot of pressure. 3. Have your facts so collected and organized that you can present them clearly in a way that even he who runs may read. 4. A bit of humor often can dispel a tense situation.

IMPORTANCE OF GOOD PUBLIC RELATIONS

The medical profession is always confronted with the problem of good public relations. These discussions are carried on at the local, at the state, and at the national levels. Pathologists have been urged to participate in and actively support the interests of their local medical society and to contribute the elements of their specialty to the improvement of the community in which they practice. In agriculture, the method of continuous crop cultivation without plowing back necessary ingredients to maintain and improve growth potentials is indeed a short-sighted policy leading to soil depletion. For another example, in various states, legislative power is urged to revise and modernize the archaic coroner's system and thereby establish the medical examiner system. The medical examiner system provides that a physician with special training in pathology, in brief a pathologist, should make the necropsy examinations. Recently during the discussions of such a revision of the Illinois statute at the legislative level, the pertinent question was raised whether the number and distribution of pathologists in the state are sufficient to meet the requirements of such a law. There seemed to be some question about this coverage. Then a factor not even suspected appeared. A coroner, serving in a large metropolitan area in the state, reported that he was unable to get pathologists to make his post-mortem examinations despite a willingness to pay a sizeable fee for this service. The reason given by the pathologists in his community was: "I am too busy." Judged by

fair economic standards, the income of these physicians is adequate and in an amount that justifies a definite professional contribution toward improving the practice of medicine in that community. When a pathologist fails to meet the responsibilities of his specialty in his community, poor public relations arise between himself and his professional associates and with the laity as well.

A program of improving work relations between the embalmers, the funeral directors, the hospital administrators, and the pathologists is under discussion in the Chicago metropolitan area so that certain forms of resistance against obtaining permission for necropsies can be eliminated. If specific examples were cited of the undue procrastination of lay employees and particularly of professional personnel in meeting their responsibilities at hospitals, most of us would feel that public relations could be improved by the pathologists. Nothing helps so much to dissolve these obstructions to a better level of practice of pathology than understanding and courtesy.

COMMENT

Many of these comments concern only principles of practice in surgical pathology and do not touch on specific tissue diagnosis. However, abilities in the latter develop through the application of principles by which experience in observation and correlation accumulates. Any medium that widens these basic elements increases the body of factual data, which the pathologist uses in meeting his diagnostic problems. I have remarked many times to associates and students that anybody can diagnose abnormalities of the "easy" tissues, but the reputation of a pathologist is determined by his ability to evaluate correctly the more difficult diagnostic problems.

Congenital Heart Disease.—The diagnostic examination of the usual case of congenital heart disease requires radiographic and fluoroscopic studies, together with a clinical examination by a physician experienced in dealing with cardiac anomalies. Cardiac catheterization, angiocardiology and aortography are reserved for cases in which the diagnosis is in doubt. The physiologist, with his specialized knowledge of circulatory dynamics, may be particularly helpful in the study of such cases. The severe degree of polycythemia which is often associated with cyanotic heart disease is prone to cause cerebral thrombosis. Hemoconcentration should therefore be avoided during the preoperative and postoperative periods and during acute febrile illnesses by maintaining adequate fluid intake. The cyanotic child must be hydrated to the precise degree which will prevent vascular thrombosis, but which will not overload the failing circulation.

Digitalis is not ordinarily used in the preoperative preparation of these patients with congenital heart disease except in the presence of overt myocardial failure. Because of the susceptibility of such patients to bacterial endocarditis, antibiotics are begun on the day preceding operation and continued for one week, or until the patient is afebrile. Despite the existence of multiple potential avenues of infection at the time of surgery, our incidence of bacterial endocarditis following operations for the tetralogy of Fallot has been remarkably low—about 2%. Most cases respond favorably to penicillin therapy. It is particularly important to give antibiotics to patients with coarctation of the aorta because infection at the suture line is usually a fatal complication.—J. V. Maloney Jr., M.D., and A. Blalock, M.D., *Problems in Cardiovascular Surgery, Annals of Internal Medicine*, January, 1954.

PEPTIC ESOPHAGITIS WITH DUODENAL OR GASTRIC ULCER

Asher Winkelstein, M.D., Bernard S. Wolf, M.D., Max L. Som, M.D.

and

Richard H. Marshak, M.D., New York

Esophagitis is probably the commonest disease of the esophagus.¹ There are many varieties of esophagitis: acute, subacute, and chronic, with a wide variety of etiological agents. Early in the 1930's, we became interested in one special group of these cases, those of peptic esophagitis. In 1934, one of us (A. W.) discussed before the American Medical Association a new clinical entity, peptic esophagitis, previously undescribed.² The association of this lower esophageal lesion with hyperchlorhydria and peptic ulcer of the duodenum or stomach led to the idea that these cases were peptic in origin, i. e., they were due to the action of pepsin and hydrochloric acid on a susceptible mucosa. At the same time, Hamperl, the Viennese pathologist, delivered a paper before the Deutschen Pathologischen Gesellschaft entitled "Peptische Ösophagitis" in which he described the pathological features of a group of cases with an erosive, stenosing inflammation of the lower esophagus.³ He stated that the early histological lesions, that is, necrosis of the surface epithelium with a separation of the superficial layers from the deeper layers of the mucosa by a fibrinoid or hyaline zone with polynuclear infiltration and hypertrophy of the muscularis mucosae, were characteristically those of peptic inflammation. Since these two early descriptions, several interesting papers on this subject have appeared in the literature.⁴ It is the purpose of this communication to describe a group of 20 cases diagnosed as this type of peptic esophagitis. It is necessary at this point to discuss the classification of peptic esophagitis, so that this special group may be demarcated clearly from the other groups of patients in whom the disease may also be peptic in origin.

Other types of esophagitis in which peptic activity (hydrochloric acid and pepsin) probably plays a prominent role are (1) esophagitis with marginal ulceration at the cardia secondary to the hiatus hernias, associated with a short esophagus (studied by Wolf and others⁵); (2) esophagitis due to severe repeated vomiting, such as occurs not infrequently after abdominal operations; (3) esophagitis due to prolonged esophageal intubation or frequent gastric lavages; (4) esophagitis secondary to operations in which the esophagus is anastomosed to the stomach (seen not infrequently after the Heyrovsky operation for cardiospasm); and (5) the solitary peptic ulcer of the lower esophagus, which may or may not be the same as the first category, or perhaps may be associated in some cases with ectopic gastric secretory tissue. These categories will not be discussed in this paper, although they are of considerable importance and will be presented elsewhere.

CLINICAL FEATURES

Apparently this disease is uncommon; however, Chevalier Jackson⁶ has pointed out that esophagoscopies are usually performed only when there is an important indi-

cation. It is probable that in patients with gastric or duodenal ulcer who have severe heartburn and acid regurgitation evidence of a mild esophagitis would be revealed if esophagoscopy with biopsy were employed in the study. Our material includes 20 cases of esophagitis with characteristic clinical, radiographic, endoscopic, and pathological features. Eleven patients were over 60 years of age, three were in the 50's, five were in the 40's, and one was in the 30's. This seems to be a disease of older persons. There were 19 men and one woman. This is an overwhelming preponderance of men.

Symptoms.—The symptoms were dysphagia (in 16 patients), heartburn (6 patients), regurgitation and/or vomiting (7 patients), substernal pain (7 patients), and loss of weight (10 patients), and hemorrhage. Dysphagia was the first and most prominent symptom in 17 of the 20 cases. The dysphagia first manifested itself as difficulty in swallowing solids. Later even liquids offered difficulties. In one case, complete aphagia occurred. In three cases heartburn preceded the dysphagia. Regurgitation or vomiting of sour fluid with or without food was a common symptom. Lower substernal pain on swallowing, without radiation to the back, was noted occasionally. Dysphagia seems to be the most constant and important symptom of a fully established peptic esophagitis. Whether heartburn, regurgitation, and substernal pain alone, without dysphagia, indicate a mild peptic esophagitis requires further study. A free acidity over 40 clinical units was chosen arbitrarily as evidence of hyperchlorhydria. This occurred in 85% of the cases. Three patients had a gastric acidity of 20 to 40 clinical units of free hydrochloric acid, 10 patients had an acidity of 40 to 80 units, and 7 had an acidity over 80 units. This finding may, of course, have etiological significance.

Complications.—The chief complications were stenosis, hemorrhage, and perforation. 1. Stenosis occurred in nine cases and was diagnosed by a combination of

symptoms (dysphagia and regurgitation), radiographic features (marked narrowing of the esophagus and some delay of the passage of barium into the stomach), and esophagoscopy (observations of swelling and narrowing and difficulty in passing the instrument through the narrow lower esophagus into the stomach). The role of inflammatory swelling, spasm, and fibrous stricture in the production of the stenosis could be determined accu-

Fig. 1.—Marked stenosis of the lower half of the esophagus with moderate dilatation above.

ately only by a study of resected specimens or postmortem material. It is probable that all three factors are involved. Fibrous stenosing esophagitis undoubtedly occurs in the late stages of the severe cases. 2. Massive hemorrhage occurred in four cases. In three it took place after the onset of dysphagia. In all cases it took the form of hematemesis. It therefore seems probable, although not proved, that the bleeding came from the esophagus rather than from the duodenal or gastric ulcer. In any general study of hematemesis, peptic esophagitis should be included as a possible cause. 3. Perforation occurred in one case; the perforation was found at the postmortem examination in a small hiatus hernia immediately below the area of stenotic peptic esophagitis (case 3). We have not seen a perforation in the stenosed portion of the esophagus.

Previous Operations.—Four patients had had previous operations for duodenal ulcer. One of these had had an operation for closure of a perforation, two had had gastroenterostomies, and one had had a subtotal gastrectomy. The symptoms of peptic esophagitis set in after the gastroenterostomy in one case and after the subtotal gastrectomy in another; therefore, it is probable that the operative procedures played a role in these two cases, possibly by furthering reflux.

Association with Ulcer and Hernia.—Fifteen patients had a coexistent duodenal ulcer and two had gastric ulcers. A gastric ulcer in one patient and a duodenal ulcer in another developed at a later date. One patient had a previous solitary peptic ulcer of the esophagus (case 4). In five cases a small hiatus hernia was found. These hernias are probably secondary, due to traction by the inflamed esophagus, as is evidenced by one case in which a hiatus hernia was not present before the esophagitis appeared, but appeared after the esophagitis was well established (case 3). In one case a larger hiatus hernia that may have been due to a preexisting short esophagus was revealed. Paraesophageal hiatus hernias were not seen in this series. As a rule, these are not associated with peptic esophagitis.

Association with Pyloric Obstruction.—It has been suggested⁷ that peptic esophagitis is prone to occur in patients with pyloric obstruction. A review of our cases with this in mind revealed the presence of pyloric obstruction before the onset of the dysphagia in only one case. It seems a somewhat surprising fact that peptic esophagitis is so rarely encountered, at least clinically, in large series of patients with pyloric obstruction due to juxtapyloric peptic ulcer.

RADIOGRAPHIC FEATURES

The roentgenologic findings are essentially of two varieties: changes in distensibility or narrowing of the lower third of the esophagus and changes in the mucosal pat-

Fig. 2.—Marked stenosis of lower third of the esophagus simulating the rat tail deformity of carcinoma in the vertical position (right).

tern (fig. 1). In the severe cases the lack of distensibility may be so marked as to produce a long segment of considerable narrowing involving the lower third of the esophagus (fig. 2). The junction between the moderately dilated esophagus above and the narrowed portion below is gradual and symmetrical. The mucosal pattern throughout the narrowed segment is distorted and may have a

7. Palmer, E. D.: *The Esophagus and Its Diseases*, New York, Paul B. Hoeber, Inc., 1952.

hazy irregular appearance. Discrete projecting ulcer craters are not seen; however, the margins of the narrowed segment may show a fine serration. Coarser irregularities are not common. The involved segment usually shows no evidence of peristaltic activity. Slight changes in caliber on repeated examinations may be noted. In the dilated segment above the involved area, there may be small irregular transitory contractions. In the type of case associated with prolonged peptic esophagitis, a very small tent-like traction hiatus hernia may be seen. This occurred in five of our cases.

In contrast to the severe cases of peptic esophagitis described above, persons with minimum inflammatory changes show considerably less striking findings on the roentgenologic examination. The failure of normal distensibility of the lower third of the esophagus may be seen only after the examination of numerous films, including those with the patient in the erect position. It can then be noted that this portion of the esophagus does not dilate as much as would be anticipated normally. Instead, when maximally dilated, a tubular cylindrical structure with parallel side walls is visualized (fig. 3). Within this segment the contours of the involved portion may show a fuzziness or a fine irregularity, and the mucosal pattern again cannot be clearly delineated. When partially empty, this segment may show irregular tertiary contractions. A phrenic ampulla is not seen. There is no significant delay in the passage of the thin barium mixture through this segment, although there may be some delay in the passage of the barium mixture from the esophagus into the stomach. Prompt regurgitation of barium was seen in two cases. Careful studies of this transcardial reflux are not available for the entire series. The differential diagnosis from marginal or peptic ulceration above a large hiatus hernia is not difficult. Marginal ulceration immediately above a large hiatus hernia associated with a short esophagus may be differentiated from the peptic esophagitis associated with duodenal or gastric ulcer by the following radiographic findings in cases of marginal ulceration. 1. The esophagus is short. 2. The area of narrowing in the lowermost end of the esophagus is short (1 cm. usually). 3. The esophagus above this area is pliable. 4. A slit-like ulcer crater or an ulcer patch may be identified immediately proximal to the cardia. 5. Transcardial reflux is marked and prompt. The differentiation from cardiospasm is usually simple radiographically. It may also be readily accomplished in most cases of carcinoma; however, in a small number of cases, differentiation cannot be made radiographically, and esophagoscopy with biopsy is then necessary.

PATHOLOGY

Gross Pathology.—The appearances on esophagoscopy are a marked edema and congestion of the affected mucous membrane. This usually involves a long segment occupying the lower half or third of the esophagus but occasionally may spread upward to involve the entire esophagus to a lesser degree. Multiple small superficial ulcerations may be seen on the surface of irregular folds. Occasionally, a larger narrow area of flat ulceration runs longitudinally immediately above the cardia on the posterior wall. When the necrotic membrane is removed, a denuded area with an intensely red granular base be-

comes visible. Small nodular excrescences or a diffuse granular appearance may be present. In addition, there may be adherent white exudates in small patches or larger plaques that are readily removed by suction, exposing an edematous mucosa. Rarely, small petechiae have been observed. There is marked narrowing of the lumen in the lower esophagus that usually can be traversed by the esophagoscope, since the narrowing is most often due to spasm. In advanced cases, however, impassable organic stenosis due to fibrous stricture formation may be encountered that requires repeated dilatations. In the early cases, the cardia seems competent, and gastric reflux is not seen. Reflux has been observed in a few cases of long duration in which a fibrous replacement of the cardia has occurred.

Fig. 3.—Earlier stage. Moderate narrowing of lower half of the esophagus with irregular edges and hazy mucosa with a small traction hiatus hernia.

Microscopic Pathology.—The microscopic features have been presented in considerable detail by Hamperl.³ He mentions as early lesions (a) epithelial necrosis, (b) epithelial hyperplasia, (c) a hyaline mucosal zone splitting the superficial epithelial layer, (d) polynuclear infiltration, and (e) hypertrophy of the muscularis mucosae. These changes are generally accepted by pathologists as evidence of peptic inflammation, that is, inflammation due to the destructive action of hydrochloric acid and pepsin on a susceptible mucosa, and form, perhaps the best diagnostic criteria of peptic esophagitis (fig. 4). In the advanced stage of the disease one sees petechial hemorrhages, erosions, infiltrations, and epithelial proliferation. Finally, fibrosis and stenosis are seen. The erosions, as a rule, do not penetrate through the muscularis mucosae. This diffuse, superficial ulceration seen in peptic esophagitis does not, in our experience,

eventuate in the deep, circumscribed solitary peptic ulcer of the lower esophagus. It should be stressed that, as a given case becomes chronic, a nonspecific type of esophagitis occasionally associated with leukoplakia may be superimposed, probably as a result of secondary traumatic and infectious agents.

THERAPY

Medical Therapy.—All of these patients were given the conventional Sippy type of therapy with anticholinergic drugs, including methantheline (Banthine) bromide in some cases, and alkalis. Six patients were treated with the continuous intraesophageal milk-soda drip therapy.⁸ Mechanical dilatation was employed in six cases. This was usually started by passing graded dilators through the endoscope. When a 36 F. dilator could be passed, endoscopic dilatation was discontinued and a 36 F. Hurst mercury-weighted rubber esophageal bougie was substituted. After a few training sessions with the therapist, the patient can usually pass this type of tube safely once daily. The size of the tube is gradually increased if possible to

Fig. 4.—Section of biopsy specimen showing epithelial necrosis, erosions, hyaline areas, polynuclear infiltration, and hypertrophy of the muscularis mucosae.

40 F. The results of this type of therapy are often strikingly good. These medical measures are usually successful and result in either a cure or a remission. We have seen a markedly constricted esophagus widen to almost normal diameter after dilatation.

Surgical Therapy.—We have used transthoracic bilateral vagotomy alone for one patient, gastroenterostomy with vagotomy for one patient, and subtotal gastrectomy for four patients.⁹ In general, the results of these operations have been disappointing. This may be due to the fact that surgery was instituted only in the severest cases with marked stenosis, hemorrhage, or intractable dysphagia. Whether the poor results are due to the persistence of free acid or to a continuation of the disease process into greater stenosis is conjectural. The fact remains that subsequent dilatations were necessary to relieve these patients from progressive stenosis. Theoretically,

the surgical procedure of resection of the lower esophagus and upper half of the stomach with bilateral vagotomy and esophagogastrostomy seems logical and should be carried out in selected cases. As yet, we have no experience with this form of therapy.

COURSE AND DIAGNOSIS

The disease had continued for 1 to 8 months in 10 cases; for 1 to 4 years in 7 cases; and for 4 to 10 years in 3 cases. Our data are insufficient to present the final radiographic and pathological results of therapy in these groups. Sixteen patients seemed to have done well with medical or surgical therapy. Three still had symptoms despite therapy, and one died of a perforation (case 3). Seven case reports are appended to illustrate the course of the disease.

The most important disease to be differentiated is, of course, carcinoma of the lower esophagus. The occurrence of peptic esophagitis in the older age group, the type of symptoms, the marked loss of weight, and the radiographic features combine to strongly suggest carcinoma. Although the radiographic features of peptic esophagitis are characteristic, they may be imitated exactly in a few rare cases by a carcinoma. Endoscopy alone may also be inadequate for the differentiation; therefore, biopsy is imperatively indicated.

Cardiospasm is usually easily differentiated radiographically and endoscopically. Other types of esophagitis may be diagnosed and separated from this group by the history and observations of definite causal agents. Such agents include prolonged vomiting, intubation, extensive burns, general infections, cerebral lesions, and chemical agents. We have also encountered a few cases of peptic esophagitis without any apparent etiological explanation. These will perhaps be clarified by the occurrence of a peptic ulcer of the duodenum or stomach later in their history. It should be stated that it is probable that mild degrees of peptic esophagitis associated only with heartburn and sour eructations may reveal no changes in the radiographic appearance of the esophagus and perhaps only slight endoscopic and histological changes.

REPORT OF CASES

CASE 1.—A 47-year-old man had had a duodenal ulcer for five years. Gastroenterostomy for pyloric obstruction was performed. Dysphagia and regurgitation were noted two weeks later. Roentgenograms showed marked constriction of the lower third of the esophagus. A biopsy specimen showed severe inflammation. Free acidity was 60 clinical units. The patient has been given liquids and ulcer medication for three years. He has gained weight and is doing well.

CASE 2.—A 64-year-old man had had a duodenal ulcer for five years. Pyloric obstruction developed. Free acidity was 52 clinical units. Dysphagia and loss of weight were noted for several months. Roentgenograms showed a narrow lower esophagus, distorted folds, serrated edges, and regurgitation. A biopsy specimen showed inflammation with hypertrophic epithelium. Gastroenterostomy with bilateral subphrenic vagotomy was performed. There was no relief of the dysphagia. Later, the patient was greatly improved by repeated dilatations.

CASE 3.—A 58-year-old man had had a duodenal ulcer for 15 years. Perforation of the duodenal ulcer eight years ago was followed by severe hemorrhage one year later. The patient had dysphagia for solids for four months. There was lower substernal pain, vomiting, and loss of weight. Roentgenograms showed irregular narrowing of the lower third of the esophagus and a penetrating duodenal ulcer. The patient's symptoms

9. Wangersteen, O. H., and Leven, N. L.: *Gastric Resection for Esophagitis and Stricture of Acid-Peptic Origin*, *Surg., Gynec. & Obst.* 88: 560-570 (May) 1949.

were relieved by intraesophageal milk-soda continuous drip therapy. A sudden perforation of the ulcer occurred a few weeks later. Two days after the suture of the perforated ulcer, sudden, severe, substernal pain and shock developed, and the patient died in 10 hours. At the postmortem examination a perforation of a gastric ulcer was found in a small piece of herniated stomach immediately below a severe stenotic peptic esophagitis. A huge callous duodenal ulcer was also present.

CASE 4.—A 60-year-old man had had dysphagia for solids, occasional vomiting, and loss of weight for five years. Esophagoscopy showed a circular punched-out ulcer in the lower end of the esophagus. The biopsy specimen showed superficial inflammation with epithelial proliferation. Roentgenograms showed a delayed emptying of the barium from the esophagus. An ulcer crater was not seen. Free acidity was 80 clinical units. The ulcer disappeared after three weeks of milk-soda drip therapy. Five months later, severe dysphagia set in. Roentgenograms showed narrowing in the lower half of the esophagus and slight dilatation above. Esophagoscopy showed esophagitis. During the next eight years the dysphagia persisted. For three years the patient was symptom free, and then he died suddenly of a coronary thrombosis. The esophagus showed inflammation microscopically but appeared grossly normal at the postmortem examination.

CASE 5.—A 42-year-old man had had ulcer symptoms for seven years. Dysphagia and regurgitation had been present for one year. Radiographs showed narrowing of the lower third of the esophagus and a gastric ulcer niche 2 cm. wide on the lesser curvature just above the angle. Free acidity was 42 clinical units. Esophagoscopy showed esophagitis and a flat posterior wall ulceration. Subtotal gastrectomy without vagotomy was performed. During the month following the recent operation he has swallowed his food easily.

CASE 6.—A 68-year-old man had had a duodenal ulcer for 20 years. For 10 years, severe heartburn and sour regurgitation were present. Three years ago, hematemesis occurred. Hemorrhage occurred again after an abdominal operation for a cecal neoplasm. Free acidity was 20 clinical units. Roentgenograms revealed a narrow lower third of the esophagus with a small hiatus hernia and a duodenal ulcer niche. The patient has been well for six months with ambulatory ulcer therapy.

CASE 7.—A 34-year-old man had had a duodenal ulcer for 10 years. Dysphagia was present for one year. Attempted transthoracic vagotomy was a failure because of adhesions. Roentgenograms showed a narrow lower third of the esophagus and a duodenal ulcer niche. The biopsy specimen showed acutely inflamed granulation tissue. Free acidity was 64 clinical units. A subtotal gastrectomy was performed. Dysphagia then became progressively worse, necessitating a jejunostomy. After several dilatations the patient improved, and the jejunostomy was allowed to close. Postoperative achlorhydria was shown by a histamine test.

COMMENT

This disease is apparently one that afflicts men in the older age groups. In the group under consideration, duodenal ulcer or gastric ulcer (and in one case a previous peptic ulcer of the esophagus) were constantly associated. From this feature, the location of the lesion in the lower third of the esophagus, and the hyperchlorhydria in most cases, the conclusion seems inescapable that this disease is peptic in origin. More important than these considerations is the histological finding of peptic inflammation. Furthermore, the response to medical and surgical anti-ulcer therapy is striking.

What the ultimate, detailed mechanism of peptic esophagitis is seems purely conjectural at present. As a working hypothesis, it may be proposed that peptic esophagitis probably commences with a more or less continuous transcordial reflux from the stomach of a highly acid peptic secretion. This reflux may result from the hy-

persecretion associated with duodenal ulcer or from an unexplained decrease in the tone of the cardiac sphincter. Perhaps the characteristic nocturnal hypersecretion with the patient in the horizontal position leads to a prolonged bathing of the lower esophagus by the highly acid gastric contents. As a result, a localized peptic esophagitis occurs in the lower esophagus with a spastic narrowing. Secondary traumatic and infectious factors then impinge in this lesion and lead to an upward extension involving one third or more of the lower esophagus. In addition there may be, especially in elderly persons with a predisposition to peptic ulcer, a disturbance in the circulatory state of the mucosa or a loss of the mucous barrier. Ectopic gastric secretory tissue was not found in this series of cases.

The disease is characterized by a long history of duodenal or gastric ulcer with a subsequent shorter history of esophageal symptoms. The chief symptoms are dysphagia, heartburn, regurgitation, substernal pain, and loss of weight. The complications are stenosis, hemorrhage, and perforation. There is no evidence that this is a precancerous disease. The response to medical therapy and mechanical dilatation is usually good. In a small percentage of the patients surgical therapy is necessary.

SUMMARY AND CONCLUSIONS

In 20 patients with peptic esophagitis 15 lesions were associated with simultaneous duodenal ulcer; 2 were associated with gastric ulcer. In one patient a gastric ulcer developed, and in one a duodenal ulcer developed. One case followed a previous peptic ulcer of the esophagus. The gastric acidity was high in 17 of the 20 patients. Transcardial reflux was noted in only two patients. The most prominent symptoms were dysphagia, heartburn, regurgitation, substernal pain, and loss of weight. The duration of the condition varied: 1 to 8 months in 10 cases; 1 to 4 years in 7 cases; and 4 to 10 years in 3 cases. Peptic esophagitis is chiefly a disease of elderly men (19 men, 1 woman); 11 patients were over 60 years of age and 8 ranged from 40 to 60 years of age. The course is relatively benign in most cases. There was one death due to perforation into the mediastinum. One patient died of a coronary thrombosis after three years of freedom from esophagitis. The chief complications were stenosis and hemorrhage. There was one perforation. Six hernias, five of which were small traction hernias, were noted.

The therapy usually consisted of medical treatment (the usual antiulcer or milk-soda drip therapy) and mechanical dilatations. Treatment was surgical in some cases. There were no esophageal resections in our series. Surgical therapy was not as successful as medical therapy plus bouginage. Partial esophageal resection plus resection of the proximal half of the stomach with vagotomy plus esophagogastrostomy seems to be the surgical procedure of choice. Four patients had had previous gastric operations. The cause seems to be the regurgitation of acid and pepsin into a lower esophagus with a susceptible mucosa. Ectopic gastric secretory tissue was not found in this series. This condition is important not only as a disease entity but also in the differential diagnosis from carcinoma of the lower end of the esophagus.

OBSERVATIONS ON ROTATIONAL THERAPY WITH TWO MILLION VOLT ROENTGEN RAYS

Hugh F. Hare, M.D., Los Angeles, Magnus I. Smedal, M.D., David Johnston, M.D.

Maurice Cote, M.D., Boston, John G. Trump, D.Sc., Kenneth A. Wright, B.S., Richard Granke, B.S.,
and

René A. Beique, M.Sc., Cambridge, Mass.

In the three and a half year period beginning October, 1949, about 500 patients were treated by rotational and multiportal methods with supervoltage roentgen rays produced at two million volts. Most of these patients had advanced malignant disease. It has become evident that the patient treated with 2 million volt radiation is usually able to accept tissue doses in the 6,000 r to 8,000 r range delivered in 35 treatment days or 7 elapsed weeks and that larger fields that include adjacent regions of lymphatic spread can be included in such treatment. Radiation sickness is markedly less than would be obtained with smaller doses of conventional radiation, and, the skin reaction is often a threshold or moderate erythema when the skin is included in the region of treatment. Moist skin reactions may be encountered in special situations such as irradiation of the folds of the skin or when the x-ray beam approaches the skin tangentially.

PHYSICAL AND BIOLOGICAL CONSIDERATIONS

Physical studies show that the roentgen rays produced by constant potentials of 2 million volts are closely equivalent in their effective wave length to the gamma rays from both radium and cobalt 60.¹ All of these radiations should therefore produce identical biological responses in tissue under similar conditions of irradiation. Compared with conventional deep x-rays, these supervoltage radiations possess clinically advantageous properties arising from their greater penetration into tissue, the relatively little scatter outside of the radiation beam, the far greater tolerance of skin at the portal of entry,² and the low ratio of bone-to-soft tissue absorption that characterizes radiation in the range of a few million volts.

The 2 million volt source of roentgen radiation used in these studies was an electrostatic accelerator of the Van de Graaff type at the Massachusetts Institute of Technology. Two such sources (manufactured by the High Voltage Engineering Corporation, Cambridge, Mass.) were available for this work, one of which is shown in figure 1. Although the radiation quality of this source was equivalent to that of the gamma rays from radium and cobalt 60, this machine accelerator possessed two impor-

tant clinical advantages: a high x-ray output in the beam greater than that of 6,000 gm. of radium or 4,000 curies of cobalt 60, and an almost "point" source of radiation that permitted sharp beam definition, with avoidance of the large penumbra that characterizes radioactive sources of even moderate output.

ROTATIONAL VERSUS MULTIportal THERAPY

That an x-ray dose could be more effectively applied by directing the beam toward the tumor from all possible angles of approach through the rotation of either the patient or the apparatus has been recognized for over 40 years. Such rotational or moving beam therapy has, however, been repeatedly discarded in the past because of the lack of a radiation capable of penetrating with sufficient intensity through the thicker body sections.

The availability at the Massachusetts Institute of Technology in 1948 of an intense source of 2 million volt roentgen rays opened up the possibility of treatment by continuous rotation. In the subsequent clinical program with the medical cooperation of the Lahey Clinic in Boston, rotational therapy has been found advantageous in the treatment of certain tumors of the brain, pituitary, pharynx, tongue, extensive cervical and supraclavicular nodes, thyroid, esophagus, bladder, cervix, and extremities. On the other hand, it is preferable to use multiple port therapy for treatment of tumors of the nasopharynx, lung, and lymphoid system and other tumors requiring very large fields or tumors located where radiosensitive regions such as the orbit or lungs must be avoided.

Figure 2 shows the patient's position and the resultant dose distribution obtained in treating pituitary adenomas by rotation using 2 mev roentgen rays. In this typical problem the sitting patient, carefully held in position by suitable supports, is rotated slowly about a vertical axis passing through the pituitary and the stationary horizontal x-ray beam of 4 cm. circular cross section is centered upon this axis at the proper elevation. The rotation of the patient (one revolution per minute or less is adequate) produces the maximum dose in a spherical 4 cm. volume, since this region is continuously traversed by the beam. Outlying regions, being in the x-ray beam only a fraction of the total time, receive a progressively lower dose the further their distance from the axis.

The advantage of rotational procedures is most conspicuous for small fields, but is still evident for the larger fields such as would be needed in delivering a radiation dose to the entire pelvic cavity. Figure 3 shows the dose distribution obtained in the typical pelvic port used in treating cervical cancer and illustrates the possibility of modifying the region of treatment with a posterior absorber to reduce the dose in the rectum and lower bowel.

BEAM SHAPING AND POSITIONING

Good therapy requires the careful shaping and positioning of the x-ray beam to include the desired treatment site with avoidance of unnecessary irradiation of normal tissue. Some of the field shapes that evolved in the course of the rotational and multiportal therapy program are illustrated in figures 4 and 5. Even with 2 mev radiation, it is feasible to adjust the aperture of the beam to the tumor-bearing region not only by the movable diaphragms that define a rectangular field but also by special absorbers and filters that further modify the shape and the intensity. By these methods it has been found possible in virtually every tumor situation that has been presented to deliver an approximately uniform dose to the primary region and the most likely invaded lymphatic regions, with reduction in the dose sustained by the surrounding tissue.

Fig. 1.—View through treatment room window of 2 million volt x-ray source (Van de Graaff type) and of rotating support for patients in rotational or multiportal therapy.

The use of radiographic films taken with the actual 2 mev x-ray treatment field has proved an invaluable procedure in insuring accurate positioning. Such films are commonly taken with the patient in the exact anteroposterior or lateral position and are usually double exposures in which a large background is superimposed upon the actual treatment field exposure. Such 2 mev radiographs have considerable diagnostic value³ and provide an excellent basis for modifying the field shape or position during the early days of treatment or for observing change in the tumor when tissue of low density or containing air passages is involved or displaced. As evidenced in figure 6, these 2 mev films show greater readability in thickness than the conventional radiograph and are free to a large extent from the scatter that accompanies diagnostic radiation. The low absorption of bone is due to the dependence of such supervoltage radiation on the atomic number of the absorber and is a tangible evidence that higher bone tolerance can be expected when such radiation is permitted to traverse bone in passing to a soft tissue tumor.

CLINICAL OBSERVATIONS

Although somewhat more than 500 patients have been treated since the start of the clinical phase of this 2 million volt x-ray study, the results must be stated in terms of palliation since the three and a half year period of use is too short for judging curability. At the outset important

decisions had to be made on the total dose necessary for the treatment of various tumors, on the period of time in which this dose could be delivered, and on the permissible volume dose that would be received by these patients when both the primary tumor and the surrounding region of lymphatic spread were included in the treatment. After

Fig. 3.—Dose distribution obtained in the rotational treatment of pelvic tumors using 2 million volt x-rays at a 125 cm. target-to-axis distance.

considerable study of the relevant literature and evaluation of our results with conventional x-ray and radium treatment, the program of dose levels and of time-dose relationships described below was with few exceptions followed throughout the subsequent period.

3. Hare, E. P., and others: Physical and Clinical Aspects of Supervoltage Rotational Therapy, *Radiology* 57: 157-167 (Aug.) 1951.

The table summarizes the clinical results obtained with the total group of patients treated up to Dec. 31, 1952, by 2 million volt x-ray radiation with the exception of those who were unable to complete their therapy because of general debility resulting from their disease. It must be remembered that at the inception of the treatment in many of these cases the disease was advanced and hope-

Fig. 4.—Typical field shapes used in rotational therapy with 2 million volt x-rays.

less by conventional standards, and a large percentage of them must be reported as "class B" cases because of previous surgery or irradiation.

DISCUSSION BY TYPE OF TUMOR

Lymphoid Tumors.—Our experience in cases of localized lymphoid tumors indicates that 2,400 r delivered to the tumor and the surrounding lymphatics is sufficient to control the recurrence of the disease in the region treated regardless of the histological type of lymphoid tumor encountered. Since these tumors usually have spread regionally at the inception of treatment, rotational therapy is less favorable than opposing portal treatment, which permits the inclusion of invaded regions with avoidance of the lungs or other uninvolved tissue.

For lymphoid tumors arising in the neck or mediastinum, which account for about 75% of lymphoid cases, we believe the entire lymphatic system of the neck, including the angle nodes of the mandible and the nodes of

Fig. 5.—Typical field shapes used in opposing port therapy with 2 million volt x-rays.

the supraclavicular, infraclavicular, and axillary region, should be treated along with the mediastinal lymph nodes. Such a field, shown in figure 5, covers not only the known tumor but the likely areas of spread. We have found that patients tolerate the treatment of these regions at a daily dose rate of 170 r measured at the mid-depth to a total dose of 2400 r at that level, delivered in about 15 treat-

ment days or 3 elapsed weeks. In such treatment of lymphoid tumors the total body dose in gram-roentgens⁴ may reach levels in the range from 20 to 40 million gram-roentgens, and we have found it desirable to make blood studies throughout the treatment period, particularly for the more extensive cases.

Of 41 patients with lymphoid tumors of various types treated in the three year period ending Dec. 31, 1952, 27 had remained clinically free of disease and 5 showed persistent or metastatic disease at the last examination; 6 had died, usually within the first six months after the start of treatment.

Carcinoma of the Thyroid.—Thyroid carcinoma has become a commonly encountered lesion in the Lahey Clinic, treatment having been given in 59 cases post-operatively, in the three year period. We believe that the entire neck and mediastinum should be treated with a total dose of 4,800 r delivered rotationally, as shown in figure 4. This dose is given in 28 treatments over a six

Fig. 6.—A 2 million volt radiograph of the neck and chest showing excellent discrimination between air passages and soft tissue, good readability in both lungs and mediastinal regions, and relatively weak bone shadows suggesting lessened bone absorption and damage.

week period at the rate of 170 r per day measured at the axis of rotation. The dose delivered to the thin and thick tissue sections is equalized by the use of a copper filter that reduces by an appropriate amount the intensity in the neck portion of the field. A posterior absorber 14 cm. wide and close to the skin is used to cut out the beam during a portion of the posterior angle of approach and thus reduce the dose sustained by the spinal cord. The total body dose for this form of treatment is usually in the range of 20 to 30 million gram-roentgens. This has not caused significant changes in the hematopoietic system.

Epidermoid Carcinoma.—The most commonly occurring tumors are of the epidermoid type. Regardless of location, it has been our plan to treat such tumors with a total dose of 6,000 r measured at the tumor center and delivered at the rate of 170 r per day for five days a week. Except for lesions of the tongue and for the primary lesions in tumors of the cervix and bladder, this dose has appeared to be adequate. In cervix and bladder tumors

4. A gram-roentgen is the amount of ionizing energy absorbed when 1 r of radiation traverses 1 gm. of tissue.

that were treated with rotational fields (fig. 4), a total dose of 6,000 r in 35 treatment days has apparently been adequate to control lymphatic spread to the pelvic nodes. In a few instances, however, it has appeared that a higher dose would be desirable for the primary lesion. These tumors are therefore now receiving 8,000 r to the primary site in the same elapsed time with the dose near the pelvic wall remaining essentially unchanged.

In general the impression has been gained that super-voltage radiation by rotation offers good palliation in this type of case and that doses potentially capable of being tumoricidal in their effect can be delivered to the entire involved region without excessive reaction from the normal structures.⁵ In the cases of cervical lesions nearly all patients experienced diarrhea that was usually controlled with paregoric or a mixture containing kaolin and pectin (Kaopectate). Cystitis was infrequent, and so far complications have been limited to a few cases in which irradiation was previously given.

Brain Tumors.—Pituitary adenomas, which are benign lesions respond well to radiation treatment. The chromophobe tumor has been encountered most frequently, but in both the chromophobe and chromophile tumors, a dose of 4,000 r has been given at a dosage rate of 240 r a day. In the rare basophile tumors we have given 5,000 r at the same daily dosage, but in these cases the sella turcica is usually well within normal size and therefore the port size can be limited to 3 or 4 cm. This represents the ideal type of tumor for rotational therapy; 64 patients with pituitary adenomas were treated in the first three years. Medulloblastomas and pinealomas respond in a similar manner as lymphomas, and in these cases a dose of 2,400 r and 4,000 r respectively has been delivered. The pinealomas can be treated by rotational therapy very satisfactorily, and, since the major portion of the tumor is localized in the third ventricle, a small port can be used. However, in the cases of medulloblastomas in which the disease may be spread through the cerebral spinal fluid or there may be multicentric origin, the entire cerebral spinal system should be included in the treatment. The total dose must therefore be given slowly, 100 to 125 r a day being the quantity that one usually can administer to such large fields. Rotational therapy is not suitable in these cases.

Nasopharyngeal Tumors.—In our series of 13 cases treated in the three year period ending Dec. 31, 1952, nasopharyngeal tumors were treated by a variety of techniques. With all techniques, however, the aim was delivery of 6,000 r to the primary lesion and its lymphatic system in 35 treatment days or an elapsed time of about 7 weeks. We believe that this lesion is not suitable for rotational therapy, since it is desirable to include its possible extension laterally to the cervical and retropharyngeal nodes and also to the neck, supraclavicular, and mediastinal regions. Figure 5 shows the two opposing lateral fields, which include the regions requiring treatment in the head and neck and the anteroposterior fields that cover the supraclavicular region and the mediastinum. A special technique is used to avoid overlap at the abutting edges of these two field systems. This treatment was tolerated very well by the 13 patients, 10 of whom remained clinically free of disease for varying times up to three and one-half years.

Carcinoma of the Breast.—A special scanning technique has been developed to treat carcinoma of the breast either postoperatively or by radiation alone. This unusual method of therapy⁶ delivers about 6,000 r to the breast and all of the immediate surrounding lymphatic system, including axillary, supraclavicular, and internal mammary nodes, and neck. The scanning method shown in figure 4 has the effect of wrapping a band of ionization around the chest wall on the involved side with little irra-

diation of either lung and usually producing only a good erythema and subsequent tanning over these regions. Of 28 patients treated in the three year period, most of them with advanced proved involvement of axillary, supraclavicular, or internal mammary nodes, 13 were clinically free of disease for up to three and a half years and 2 had persistent or metastatic disease.

6. Hare, H. F.; Trump, J. G., and Webster, E. W.: Rotational Scanning of Breast Malignancies, *Am. J. Roentgenol.* 68: 435-447 (Sept.) 1952.

Bronchogenic Carcinoma.—Bronchogenic carcinoma was treated in 43 cases with 2 million volt x-rays⁷ with opposing anteroposterior ports of such shape as to include the mediastinum, the involved portions of the lung, and the supraclavicular regions. Doses up to 6,000 r delivered in 35 treatments were usually accompanied by relief of symptoms and regression or disappearance of the lung lesion. This therapy was followed in about six months by a mild to severe pneumonitis, which in a few cases was difficult to manage. Of the first 19 patients treated by radiation alone, 2 with advanced bronchogenic carcinoma remained asymptomatic for over 30 months. When possible, our present plan is to deliver first to the entire involved region a dose of 3,000 to 4,000 r. Then the lung is removed surgically to obviate late complications and permit histological evaluation of the radiation effect. Then the radiation therapy is continued until 6,000 r has been administered. Although this new plan is too recent for evaluation, it has become evident that this preoperative radiation renders operation feasible in some borderline cases. Of 43 patients treated by radiation alone or postoperatively or with intervening surgery, 20 were clinically free of disease for varying periods from 4 to 32 months.

Bone Tumors.—A small number of osteogenic sarcomas were treated during this period, most of them with 6,000 r to 9,000 r delivered in 35 to 50 treatment days. Figure 4 illustrates the method of treating the extremities rotationally when this or other types of disease are present. It is believed that 2 million volt x-rays are particularly favorable for treating tumors involving bone because, unlike conventional deep therapy radiation or ul-

tra-high-voltage radiation, this radiation is not selectively absorbed by the calcium component of the bony structure. Such 2 million volt radiation thus delivers its biological effect to the invaded soft tissue elements without excessive energy absorption in the bone. We have the clinical impression, as has been observed in radium beam therapy, that the tolerance of bone for 2 million volt x-rays is significantly greater than with conventional radiation.

SUMMARY

In the treatment of about 500 patients with 2 million volt x-rays by rotational or multiportal methods, it has been found possible to deliver more adequate doses to the primary lesion and the adjacent lymphatic system. Rotational treatment has been found advantageous for many of the more localized tumors such as those of the pituitary, larynx, esophagus, thyroid, breast (by scanning), bladder, cervix, and the extremities; on the other hand multiple or opposing ports are believed to be better in the treatment of advanced lymphoid lung, abdominal, and other tumors when very large fields are involved or when certain regions such as the eyes or the lungs must be protected. Because of the greater penetration, freedom from scatter, and high skin tolerance of 2 million volt x-rays, the patients tolerated more adequate treatment with less radiation sickness and less skin reaction than would be obtained with conventional deep x-ray therapy. The technique for careful x-ray beam shaping and positioning and the diagnostic value of 2 million volt radiographs are pointed out.

DERMATITIS OF THE HANDS DUE TO HOUSEHOLD CLEANERS

Matthew J. Brunner, M.D., Chicago Heights, Ill.

Eczematous eruptions of the hands have always constituted an impressive proportion of all dermatological cases. As with other eczemas, eczemas of the hands have a varied etiological background, but it appears that an increasing number are being seen in housewives, among whom the factor of external irritation from cleansing agents used in housework may be of prime importance.¹ Of 145 cases of nonspecific eczematous dermatitis of the hands seen in the past 12 months, 108 were in housewives. The duration of the condition at the time of examination varied, but many of these patients had had an eruption on the hands, intermittently or continuously, for years. Few eruptions could be cleared in less than four weeks, and some required up to three months

of treatment. In view of the frequency and relative chronicity of this type of dermatitis, it deserves special consideration, and the possible causative role of household detergents as excitants of dermatitis in housewives also requires clarification.

CLINICAL FEATURES

Most cases conform to the description of housewives' eczema as given by Sulzberger.² They begin "with mild dryness, redness and scaling, which as the condition becomes more severe under continued exposure to soap and water, leads to fissuring and crusting, and eventually to vesiculation and ultimately to thickening and lichenification." The first reaction is often on the sides of the fingers and in the webs and occurs with special frequency on the left fourth finger, under the rings. In a well-established case, there is often a combination of erythema, scaling, fissuring, and acute vesiculation and edema in different areas on the dorsa and sides of the fingers (fig. 1) and the dorsa of the hands (fig. 2). Complicating monilial infections are occasionally seen, but ordinary pyogenic infection is commoner and is exhibited as pustulation, cellulitis, and even lymphan-

gitis. In old cases, discrete rounded vesicular or exudative eczematous patches may develop and simulate nummular eczema. During exacerbations of the dermatitis on the hands, an eczematid may appear as a diffuse papular or patchy eruption, usually on the forearms, arms, or face, but occasionally this becomes generalized. Extreme pruritus, burning, and discomfort are common complaints. In a large proportion of the cases, a previous diagnosis of fungus infection or neurodermatitis

Fig. 1.—Dermatitis of dorsa and sides of fingers.

had been made, and irritant or sensitization dermatitis resulting from inappropriate medication was superimposed on the original eruption.

Systematic questioning of patients revealed that subjective irritation or actual flare-ups of the already established eruption were repeatedly caused by the following materials: soaps, synthetic detergents, hot water, solvents (as in waxes and polishes), juices of orange, tomato, potato, and onion, stimulating or keratolytic preparations, ultraviolet light or sunlight, and x-rays in the acute phase. The condition was also aggravated by macerating influences, such as hyperhidrosis, especially during prolonged wearing of protective rubber gloves or prolonged soaks or wet dressings, and heavy applications of greasy occlusive ointments. Circulatory influences, including exposure to heat, alcohol ingestion, and emotional upsets, also caused aggravation.

Close observation of the clinical course suggested that the usual persistence of the eruption, even after contact with detergents has been stopped, is probably largely due to failure to recognize the role of these secondary irritating factors in perpetuating the inflammatory reaction. In this connection, special notice should be given to the importance of emotional upsets as exacerbating influences. Many patients reported flare-ups of the eruption immediately after a disagreement within the family or with other relatives, the

serious illness of a child, or some other domestic crisis. These reactions may be explained as effects of the circulatory changes in the skin that accompany emotional stress. Increased permeability of cutaneous capillaries has been shown by Kepecs, Robin, and Brunner³ to occur during hypnotically induced emotional stress. Significant increases were produced in the rate of exudation from an experimental cantharides blister under these conditions. Similar emotionally conditioned circulatory changes, with resultant exudation and edema, can perhaps accentuate already present inflammatory phenomena in clinical cases. Hyperhidrosis of emotional origin is also important as an aggravating factor in occasional instances.

TREATMENT

Treatment of housewives' eczema is based on these premises: that the eczema is primarily due to external irritation, that the inflamed skin is hyperirritable, and that it will react to certain influences and agents innocuous to intact skin. Obviously, all such irritants must be avoided if the dermatitis is to heal. For this reason, many of the conventional therapeutic agents have been discarded, such as coal tar and keratolytic preparations, x-ray therapy in the acute stages, ultraviolet radiation, and prolonged wet dressings or soaks. Although helpful in some cases, all of these were found to cause exacerbations frequently. At the first visit, the concept of the dermatitis as a reaction to external irritants is impressed

Fig. 2.—Appearance of dermatitis on dorsum of hand.

on the patient, so that cooperation will be given in the rigorous regimen that must be followed. The patient is urged to do only a minimum amount of housework, to send out her laundry, and to enlist the aid of her husband or children in dishwashing, and other kitchen duties. Contact with these and the agents previously cited is banned.

3. Kepecs, A., Robin, M., and Brunner, M. J.: Relationship Between Certain Emotional States and Exudation into the Skin, *Psychosom. Med.* 13:16-17, 1951.

and "wet work" can be done only while wearing protective rubber gloves. Rubber gloves are best worn with separate inner cotton gloves, although gloves lined with fabric may be substituted. Since even mild toilet soap generally produces irritation, the patient is directed to wash only with a tepid solution of Aveeno (a concentrate of the gum fraction of pure oatmeal) or boric acid.

Fig. 3.—In tests of irritant properties of detergents, dryness, scales, and fissures developed after four or five daily washings.

Cosmetic cleansing creams are sometimes useful. Topically, petrolatum, boric acid ointment, zinc oxide ointment, or Lassar's paste, with or without a small amount of ichthammol (Ichthyol) or naphthalan, are generally safe. They may be applied as often as desired, but to avoid irritation they must be spread thin and not rubbed in vigorously. For "id" eruptions, a bland shake lotion is acceptable. X-ray therapy is withheld until vesicula-

Fig. 4.—Reaction resulting from a five hour patch test with 4% sodium alkyl sulfate.

tion and exudation have subsided. Where secondary infection is manifest and is suspected, antibiotics are given orally and sometimes produce spectacular improvement. Oxytetracycline (Terramycin) or chlortetracycline (Aureomycin), in a dose of 0.75 to 1 gm. daily given for five to seven days, are preferred over topical application of antibiotics. If the factor of emotional tension appears important, administration of sedatives, such as phenobarbital, is useful. With this simplified

regimen, exacerbations caused by treatment are rare, and the incidence of suddenly developing eczematid eruptions is reduced to almost nothing, although in my experience this complication was not infrequently the first result of standard treatment methods. For a widespread eczematid that does not respond quickly to treatment, the use of cortisone by mouth in a dosage of 100 to 150 mg. daily will generally give relief. However, corticotropin (ACTH) or cortisone should not be employed as substitutes for dermatological management. Recurrence of the dermatitis after the hormones have been discontinued is usual, unless topical therapy and the program of avoidance of irritants are used concurrently.

COMMENT

Most household detergent compounds are based on anionic wetting agents, either natural (soap) or synthetic. Of the synthetics, the alkyl sulfates, alkylaryl

Fig. 5—A, results of soaking keratin scales in water and, B, in detergent solution showing swelling of cells ($\times 179$).

sulfonates, sulfated amides, and sulfated fatty acids monoglycerides are probably most widely used. Many detergent compounds also contain high percentages of inorganic salts, such as sodium sulfate, tripolyphosphate, or pyrophosphate, and the pH of different compositions ranges from neutrality to approximately 10.5. Optical bleaches, carboxymethylcellulose, perfume, and other materials are also incorporated. Although no attempt has been made to compare systematically all the different types, preliminary study indicates there can be considerable variation in their cutaneous irritant properties.

Evaluation of the irritant powers of these agents has been carried out by means of a simulated usage test. This included soaking the hands in a solution of wetting agents of 2 to 4% concentration at 45 C (138.6 F) for 20 minute periods on successive days. Progressive alterations in the skin developed in approximately 30% of 23 test subjects who used one particular agent. Dryness, scaling, and slight fissuring developed first, usually after four or five applications, while redness and pruritus appeared in some subjects with continuation of the soakings (fig. 3). Similar findings were obtained by Bober^{1a} who used a daily repeated scrubbing technique to demonstrate the irritating powers of detergents. Persons with dry skins appear to be predisposed to reactions, particularly during winter weather, when there is already some chapping. Results of patch tests (by means of a modification of the method of Emery and Edwards⁴) did not contradict these findings, since a single five hour application of 4% solution of a sodium alkyl sulfate produced reactions in 23 of 36 subjects (fig. 4). Reactions varied from erythema to vesiculation and lasted up to 10 days. Added to these findings, is the oft-repeated clinical observation that recurrence of dermatitis in housewives follows reexposure to household detergents. It can be stated then that, under actual or simulated usage conditions, the detergents tested produce reactions in some subjects; that the intensity of the reaction varies depending on individual resistance; and that repeated contact is usually needed to develop the reaction under use conditions. All the reactions noted were of the direct irritant variety. Although allergic eczematous sensitization to these agents can occur, it was seen only rarely in the cases studied.

Little is known about the mechanism of skin irritation by wetting agents; certainly removal of fat from the skin or neutralization of the acid mantle, the favored theories, cannot explain all the findings. For example, one of the most irritating agents studied had a pH of only 6.5, and, in a number of instances, skin pH showed little change from previous levels after soaking in detergent solutions known to be capable of producing irritation. No direct relationship was noted between fat emulsifying power and irritancy; on the contrary, preliminary studies suggest that both soaps and synthetic anionic detergents act by forming complexes with keratin of the stratum corneum and increasing its power of water imbibition and producing considerable swelling (fig. 5). Subsequent to this marked swelling, loss of coherence of the stratum corneum and resultant scaling or fissuring may be seen. These agents exert a similar but even greater effect on the less cross linked, more soluble prekeratin of the cells of the lower portions of the epidermis than on the relatively inert, fully cross linked keratin of the stratum corneum. Their action on the lower, living portion of the epidermis is the more important one, since inflammation is a reaction of the host to damage sustained only by living cells.

The power of the detergent to penetrate through the stratum corneum to the lower, living levels of epidermis is a major factor in determining the degree of damage.

As in other chemical interactions, the concentration and temperature significantly alter the rate of reaction. (This work will be reported in detail later.) The final effectiveness as a denaturant depends, however, on the molecular structure of the agent.⁴

SUMMARY AND CONCLUSIONS

Evidence can be accumulated that the so-called housewives' eczema is basically an external irritant dermatitis resulting from contact with cleansing agents used in housework. Studies suggest that some of the synthetic detergents used in housework may irritate; however, it cannot be assumed from this finding that such agents are the entire cause of clinical cases of dermatitis of the hands in housewives. Many other known irritants are also used, such as ammonia water, hypochlorite bleaches, phosphates, abrasive powders, and organic solvents in waxes and polishes. All of these may contribute to the production of dermatitis in varying degrees in different instances. Not only these substances but also the exacerbating influences previously cited must be avoided if permanent cure is to be effected. A regimen of strict avoidance of external irritants, along with bland, nonirritating topical therapy is generally successful. Recurrences are not infrequent after reexposure to household irritants, however, and patients should be instructed to continue use of rubber gloves for dishes and laundry work as a permanent measure. Similar eruptions may also be seen in bartenders, soda jerks, and others in occupations involving "wet work"; the mechanisms of production of the dermatitis and methods of treatment are identical.

Cardiovascular Surgery.—It is no longer adequate to state simply that the patient has congenital heart disease or acquired heart disease; the type of deformity must be determined. Whereas advances in diagnosis have increased the scope of surgery, so have the findings at operation added knowledge which increases the accuracy of diagnosis. Much may be learned at the time of operation by palpation of the exterior of the heart and great vessels and even more, in some instances, by inserting a finger into the interior of the heart. For example, digital exploration of the mitral valve through the left auricular appendage has emphasized the difficulties in differentiating by auscultation between mitral stenosis and insufficiency, and has caused some cardiologists to alter their interpretation of heart sounds. An important point is that knowledge has been extended rapidly by the combined efforts of physicians and surgeons. The surgeon can certainly profit from the mature judgment of the physician. We make a plea that you do not regard your fellow colleague as a mere technician. As a result of his opportunity to correlate clinical findings with the actual mechanical dysfunction of the heart as determined at operation, the surgeon has developed considerable skill in the evaluation of certain aspects of cardiovascular disease. . . . The advice and help of the radiologist and anesthesiologist with their knowledge of heart disease are invaluable.—J. V. Maloney Jr., M.D., and A. Blalock, M.D., *Problems in Cardiovascular Surgery, Annals of Internal Medicine*, January, 1954.

SURGICAL TREATMENT OF EMERGENCIES OF THE HEART AND VESSELS IN THE THORAX

Frank Gerbode, M.D., San Francisco

Of all the emergencies affecting the heart, cardiac arrest requires the most urgent treatment. Anoxia, vagal stimulation, anesthetic agents, unexpected reactions to drugs, and manipulation and displacement of the heart have been shown to be at fault, but frequently no apparent reason can be found.¹ Failure to recognize and successfully treat cardiac standstill or fibrillation within three to five minutes will usually, at best, result in permanent central nervous system changes.² Experience has shown that too often it is wasted effort to rely on the administration of cardiac stimulants through the intact thoracic wall. If this method has been tried and no perceptible return of cardiac function is apparent in a minute, one should waste no more time but proceed with thoracotomy through the left fourth interspace, cutting costal cartilages to gain exposure. Oxygen should be administered, preferably through an intratracheal tube; but, until the tube is in place, a face mask may be used to gain a positive pressure system. It is far better to open the thorax at once, without preliminary sterile precautions, unless they are immediately at hand, for the possibility of infection is much less important than the necessity for prompt restoration of the circulation.

One cannot determine, without making an electrocardiogram in each instance, whether the circulation has failed because of standstill or fibrillation; therefore, one must expose the heart, through the open pericardium, in order that the proper treatment can be applied. If ventricular fibrillation is present, it is best to use an electric defibrillator to establish a normal rhythm (fig. 1). It is probably advisable also to inject a solution of procaine amide or procaine into the chamber of the right ventricle while the defibrillating machine is being readied, meanwhile maintaining the circulation with rhythmic compression of the heart. Cardiac standstill is treated by rhythmic compression of the heart with the aid of calcium chloride solution, 10 cc. of a 10%, or 0.5 cc. of a 1 in 1,000 solution of epinephrine in 10 cc. of isotonic sodium chloride. Here, too, it is best to inject the solution into the right ventricle or pulmonary artery, for there will then be a gradual passage of the drug into the coronary vessels as it returns from the pulmonary vascular bed. Epinephrine encourages ventricular fibrillation; therefore, it must not be given in large doses and should probably be given in conjunction with procaine or procaine amide. When cardiac arrest is diagnosed, those at hand must proceed with resuscitative measures; for, although one may send for an expert, time is so precious that it is best not to wait for him to arrive.

CONTUSION OF THE HEART

Contusion of the heart caused by automobile and industrial accidents may be evidenced by cardiac irregularity or electrocardiographic changes suggestive of coronary occlusion.³ Under such circumstances, the persistence of shock or the added burden of an operation under general anesthesia may favor coronary thrombosis. Treatment is usually best in the hospital, where there is recourse to oxygen, proper diagnostic aids, and special nursing. In general, these patients should be managed as though coronary infarction had, in fact, occurred.

Although attempted suicides through self-stabbing with sharp objects have given way to more certain methods, there are still many instances of stabbing with knives and sharp objects, usually inflicted by others; and occasionally such instruments become impacted in bone. It is doubtful whether a sharp weapon that is impacted in the region of the heart or great vessels should ever be removed before direct exposure of the involved deeper structures has been accomplished by thoracotomy. Failure to regard this precaution might lead to fatal hemorrhage.

CONTROL OF HEMORRHAGE

Many wounds of the great vessels within the thorax undoubtedly end fatally before treatment can be instituted. Not infrequently the wound of entrance is small and misleading and does not indicate the seriousness of the internal injury. Direct means of controlling serious bleeding are not available without open operation, as contrasted to extremity wounds in which the source of hemorrhage is obvious and capable of direct control. In continued intrapleural bleeding, the hemorrhage is due, usually, to lacerated intercostal or internal mammary vessels. If the hemorrhage is persistent, open operation is imperative to secure or repair the bleeding vessels. Bleeding from the lung usually subsides because of pulmonary collapse and the compressing effect of the hemothorax itself.

It must be remembered that 1,000 to 1,500 cc. of blood may be aspirated and, with blood replacement, operation will still not be required. Early and repeated aspiration of the hemothorax is indicated, without replacement by air, to permit early expansion of the lung.⁴ Massive clotting may occur as early as four to six hours after accumulation and preclude removal by aspiration. Observations during the recent war showed that from 15 to 20% of hemothoraces resulting from war injuries (and 5 to 10% of civilian) progressed to a chronic stage that required operative treatment, but enzyme treatment will no doubt reduce this number.⁵ Liquefaction of the clotted hemothorax by the use of these enzymes has some enthusiastic support. If a large organized clot persists after three to five weeks, however, decortication is in order.

Injuries to the vessels arising from the aortic arch may demand maximum skill and ingenuity to bring bleeding under control. One should not hesitate to resect the

clavicle in order to expose and control the carotid, subclavian, or innominate arteries.⁶ In some situations it is more feasible to perform median sternotomy in order to obtain an adequate exposure of the superior mediastinum to gain access to the origin of these vessels. It should also be remembered that proximal ligation of the subclavian arteries can be accomplished through anterior intercostal incisions, and this may be the wisest preliminary move when proximal ligation of these vessels is indicated.

ACUTE COMPRESSION OF THE HEART AND TAMPONADE

Acute compression of the heart has been the subject of study by numerous investigators, so that now there are explanations for most of the physiological alterations accompanying it.⁷ Beck has described the triad for acute compression of the heart as consisting of (1) quiet heart, (2) rising venous pressure, and (3) falling arterial pressure; it is also characterized by the presence of a paradoxical pulse. Filling of the right ventricle is dependent on the effective venous pressure, which in turn can be influenced markedly by an increase in intrapericardial pressure. In chronic compression the effective venous pressure may be considerably higher than it is in acute compression before the same degree of disability is produced. Under acute conditions, such as exist with hemo-pericardium from a stab wound, serious reduction in cardiac output may occur when the pericardial pressure is between 100 and 150 mm. of isotonic sodium chloride.

It is often said that acute cardiac compression is accompanied by a small heart. This is true, but the usual finding is that the cardiac silhouette and percussible border are enlarged, due to the presence of the fluid that is causing the disability. The heart is small, due to the compression by the surrounding fluid, but the physical and roentgen signs are of cardiac enlargement. One cannot determine the exact size of the heart under these circumstances without removing the pericardial fluid. Fluoroscopic and kymographic observations of the cardiac borders show diminished excursion. The low cardiac output causes a state resembling shock; inadequate circulation to the brain causes cerebral anoxia, unconsciousness, and at times incontinence. The neck veins are distended, and the venous pressure is high.

The initial treatment of acute tamponade resulting from a penetrating or perforating wound of the heart is usually conservative. An infusion of isotonic sodium chloride or blood is started and maintained during the period of observation.⁸ Aspiration is done with a long 16 or 18 gage needle either parasternally in the left fourth interspace or to the left of the xiphisternum. The preliminary trial at simple aspiration has developed from the experience of numerous surgeons who have demonstrated amply that this treatment alone frequently is lifesaving.⁹ Repeated aspiration often is necessary, and it is a common observation that the withdrawal of only a small quantity of fluid results in a miraculous recovery. This reversal of a desperate status may be only temporary, however, and one must constantly be alert to the possibility that within a few hours or less tamponade may recur and require further treatment. It is advisable to have the patient in the operating room during this ex-

tremely vital period, with preparations in order for thoracotomy, should the bleeding continue after two or three aspirations. It is to be expected that wounds caused by small, sharp objects would be less likely to cause serious bleeding than those due to firearms and large knives. A lacerated coronary vessel may cause rapid or slow filling of the pericardial space, depending on the caliber of the vessel, and on whether it is incompletely or completely severed. Under some circumstances the blood may clot, and the presence of the hematoma, with continued bleeding, may require open operation; for it may then be impossible to aspirate the blood. It is common to find some hemothorax, and this may require aspiration.

Intrapericardial tumors and infectious processes may cause pericardial effusion and tamponade.¹⁰ Under such circumstances aspiration is indicated as a preliminary step not only for relief of cardiac compression but also to establish the diagnosis through cytological and bacterio-

Fig. 1.—Electrocardiogram of a man being operated on for mitral stenosis. Ventricular fibrillation began just after the pericardium was opened and followed simple palpation of the heart. Electric defibrillation was successfully performed, and a valvotomy was done. The patient showed no ill effects from the ventricular fibrillation. Note the warning tachycardia that preceded the onset of ventricular fibrillation.

logical examination of the fluid. Injection of a small quantity of air may aid in making the diagnosis. Effusions from growths are best treated by making a dependent opening in the pericardium so that the fluid will drain into the pleural space. If drainage is necessary in purulent pericarditis it should be external. Hydropericardium may be caused by perforation of the esophagus from swallowed foreign bodies, esophageal ulcer, or trauma that has torn the pericardium and allowed air to enter from the pleural space. Foreign bodies may cause posterior esophageal perforations and then erode the aorta, producing fatal hemorrhage.

REMOVAL OF FOREIGN BODIES

A foreign body that penetrates the thorax and lodges in the heart or great vessels may follow a variety of peculiar courses.¹⁰ If it lodges within the lumen of a vein, it

tends to gravitate toward the heart, if in an artery, it is likely to leave the thorax and be found in a peripheral artery. There are recorded instances, however, of metallic fragments that have been pulled into the inferior vena cava and iliac veins by gravity. Occasionally a shell fragment or bullet may be impinged in the spine and temporarily plug a rent in an artery or vein, with subsequent

Fig. 2.—Oblique roentgenogram of the thorax of a marine who suffered a penetrating bullet wound through the sternum. The bullet was removed from the region of the heart between the aorta and pulmonary artery; it had been surrounded by edema and inflammation and had threatened erosion of the vessels.

hemorrhage from pressure necrosis or infection. Serious hemorrhage may occur when such foreign bodies are removed at operation if suitable precautions for proximal and distal control of vessels are not made. An example of the peculiar migration of a bullet was given by a man who suffered a penetrating wound in the left shoulder. There was a large hematoma around the clavicle, and an absent left radial pulse. Roentgen examination of the thorax failed to show the presence of the bullet. Subsequently the patient complained of coldness and pain in the left leg, and further studies revealed that the bullet had lodged in the left common femoral artery, from which it was removed with eventual complete recovery. Undoubtedly it had entered the aorta through the left subclavian artery, lost its force, and was carried downward by the blood to the distal artery.

Removal of retained foreign bodies from the region of the heart and great vessels became almost a commonplace procedure during and after the last war.¹¹ In competent hands there is practically no mortality from such operations, leaving little to favor an attitude of non-removal of foreign bodies that are causing few or no symptoms. Quite apart from the psychological aspects of retained metal there is always the possibility of recurring

endocarditis, pericardial effusion, pericarditis, and aneurysm. Furthermore, such retained foreign bodies may be asymptomatic until sudden erosion of the heart or great vessels occurs. It is usually easier to recover those that have been in situ for a time than it is just after they become lodged, for hemorrhage and edema obscure landmarks. Large foreign bodies are more dangerous than small ones; and irregular, jagged ones are more apt to erode than smooth ones.

REPORT OF CASES

CASE 1.—A 26-year-old marine suffered a penetrating gunshot wound of the sternum while he was in combat in North Korea. There was only minimal immediate discomfort and disability, and roentgenograms showed that the bullet lodged in the upper portion of the heart (fig. 2). Subsequently, there was some infection of the sternum that responded to curettage and antibiotics. Six weeks later, while the marine was on sick leave at home, pericarditis developed, requiring hospitalization and treatment with antibiotics. After recovery, operation was performed through an intercostal incision, and the jagged bullet, surrounded by edematous and inflamed tissue, was found embedded in the heart between the origin of the aorta and pulmonary artery. It soon would have caused erosion and sudden fatal hemorrhage. Removal of the bullet was followed by the patient's prompt recovery and return to duty.

CASE 2.—A marine was wounded in action on Aug. 17, 1950, in Korea. The bullet entered the right anterior thorax, causing a massive right hemothorax. Early treatment consisted of transfusion and aspiration of the hemothorax. Roentgenograms revealed the bullet lying in the posterior portion of the left side of the heart (fig. 3A). The marine was subsequently evacuated to the U. S. Naval Hospital, Oakland, Calif. He then had signs of heart failure with generalized edema, enlarged liver, and ascites. There was a loud continuous murmur to the left of the sternum, loud systolic and diastolic murmurs in the aortic area, and blood pressure of 138/40 mm. Hg, indicating either an incompetence of the aortic valves or a large fistula involving the aorta. After two weeks of preparation during which there was only slight improvement, a thoracotomy was performed on Sept. 19, 1950, with the hope of closing the fistula and possibly recovering the missile. At operation it was apparent that the fistula was within the heart and not accessible to closure; the bullet was not recovered. The patient's postoperative course

Fig. 3.—A, roentgenogram of the chest of a marine, showing the resolving hemothorax, enlarged heart, and the position of the bullet. B, photograph of the heart of the marine, who died five weeks after suffering a penetrating wound from the bullet. The bullet had passed through the right atrium into the subaortic area, where it had lacerated an aortic cusp, and lodged in the wall of the left ventricle.

was progressively worse, with death from heart failure five weeks after injury. Necropsy revealed that the bullet had passed through the right atrium into the subaortic area, had cut an aortic valve cusp, and then had become embedded in the wall of the left ventricle (fig. 3B). Death was due to a right atrium-subaortic fistula and aortic insufficiency.

AORTIC ANEURYSMS

Aortic aneurysms continue to challenge the skill and ingenuity of each generation of surgeons. Although surgical progress in this field has been slow, we now have three methods of dealing with thoracic aneurysms. The instillation of long lengths of fine wire into saccular aneurysms is still being utilized, and the results of such treatment are occasionally satisfactory. Under favorable circumstances, wrapping the aneurysm with polythene film impregnated with dicetyl phosphate will cause the deposition of a fibrous envelope, and help to prevent expansion.¹² An aneurysm that threatens to burst through the thoracic wall may be halted by wrapping its neck with this material, causing gradual occlusion and thrombosis of the sac. It is now apparent, however, that, if the adjacent aorta is not too badly diseased and if adequate dissection is possible, it is feasible to resect some saccular aneurysms involving the aortic arch, with repair of the base by arterial suture.¹³

The technical feasibility of resecting a segment of the descending or thoracic aorta containing an aneurysm complicating a coarctation has been demonstrated.¹⁴ Here, there is a rich collateral circulation that permits total aortic occlusion during the repair. But, in the presence of an acquired thoracic aneurysm, without coarctation, there is no established collateral to maintain the viability of the spinal cord or to ensure renal function. Experimental shunting procedures have been utilized to

avoid this difficulty, and on one occasion a lucite tube was used to maintain the circulation while a graft was sutured in place.¹⁵ As yet there is no satisfactory treatment for dissecting aneurysm.

SUMMARY AND CONCLUSIONS

When the diagnosis of cardiac arrest is made, prompt resuscitative measures should be instituted by those immediately in charge of the patient. Contusion of the heart is treated as though infarction had occurred. Wounds of the vessels arising from the arch of the aorta may require median sternotomy, resection of the clavicle, or intercostal thoracotomy for proper exposure and control of hemorrhage. Hemothorax is treated conservatively by repeated aspiration unless the bleeding is continuous or massive. Cardiac tamponade is best treated by aspiration unless it recurs or is persistent; then thoracotomy is indicated. In general, most foreign bodies that become lodged in the region of the heart or great vessels should be removed, regardless of whether they are causing symptoms. Failure to do so may lead to pericarditis, erosion of the heart or great vessels with serious hemorrhage, or aneurysm. Although there is no satisfactory surgical treatment for dissecting aneurysm, other aneurysms involving the thoracic aorta or its great vessels may at times be satisfactorily controlled by wiring, wrapping with reactive polythene film, or under favorable circumstances, resected. Whenever feasible, the latter treatment is to be preferred.

INJURIES OF THE CHEST WALL

Donald L. Paulson, M.D., Dallas, Texas

Injuries to the chest may be penetrating or nonpenetrating, depending on whether a wound through the chest wall has occurred. The penetrating wounds are divided into closed penetrations and sucking wounds. Nonpenetrating injuries, resulting from a blow to, or severe compression of, the thorax, usually involve fractures of the bones of the chest wall and shoulder girdle. A penetrating wound of the chest may involve injury to one of the intercostal or internal mammary vessels, the lungs, the heart, or great vessels. Sucking wounds require prompt closure by any means. Occlusive dressings should be used until adequate surgical facilities become available. Large traumatic defects in the chest wall may be closed by means of periosteal or perichondrial flaps or by steel wire mesh. The associated pneumothorax or hemothorax must be treated by appropriate measures.

Nonpenetrating injuries of the chest are steadily increasing in incidence due to the present modes of travel at high speed. Those injuries that result from severe compression of the thorax are commonly referred to as crushed chest, stove-in chest, or flail chest. They are frequently associated with trauma to the head, extremities, and abdominal and thoracic viscera and carry a high mortality. The shearing force of these injuries may produce contusion of the myocardium; rupture of the diaphragm, bronchi, or aorta; or chylothorax. Severe

respiratory embarrassment results from interference with normal chest wall motion, contusion and edema of the lung, pneumothorax, or hemothorax.

Wood¹ has demonstrated that after even minor injury of the chest wall, such as a fracture of a single rib, there is a marked reduction in oxygen absorption on the affected side. Thus, even though no ribs are fractured, as a result of severe bilateral compression of the chest wall with painful splinting of the intercostal musculature, the ventilation of both lungs is reduced. Concomitantly acute pulmonary hypertension with transudation of fluid into the lung results from closure of the vascular bed surrounding the poorly ventilated alveoli. This course of events, sufficiently severe, may result in death, because of pulmonary edema alone. Also, pneumothorax, hemothorax, paradoxical motion of the chest wall, and pendulum respiration, with collection of blood and fluid in the tracheobronchial tree, combine further to diminish alveolar ventilation and compound the pulmonary edema. How long the person can stand this depends on his respiratory reserve and the severity of the injury.

1. Wood, N.: cited by Jensen, N. K.: Recovery of Pulmonary Function After Crushing Injuries of the Chest, *Dis. Chest* 22: 319, 1952.

TREATMENT

Minor injuries, usually involving the fracture of one or a few ribs, in which the loss of pulmonary ventilation is still within endurable limits, may be treated simply by methods that will prevent further loss of function. The progression of anoxic pulmonary edema may be prevented with oxygen supplied by mask or nasal catheter. Pain is relieved by a paravertebral block of the intercostal nerve segments involved, as well as those adjacent to them above and below. This may be repeated as often as necessary. Adhesive strapping is to be avoided as ineffective.

The patient is encouraged to cough, but he is often unable to do so effectively. Repeated intratracheal aspiration by means of a catheter or even bronchoscopy is usually indicated to prevent the development of increasing atelectasis. Antibiotics are administered. Sedation should be kept at a minimum lest the patient drown in his own secretions. Barbiturates are to be avoided entirely, and only small doses of opiates should be used. Delayed pleural effusion, the late development of pneumothorax, and evidence of cardiac contusion are to be carefully watched for by means of serial electrocardiograms.

Severe crushing injuries rapidly result in dangerous ventilatory insufficiency. The treatment of these injuries consists of the elimination of paradoxical motion as a factor in inefficient ventilation, the maintenance of an adequate airway by repeated removal of tracheobronchial collections of blood and secretions and the relief of pain.

Stabilization of the chest wall may be very difficult. Adhesive strapping is ineffective and reduces vital capacity. Skeletal traction by means of screw hooks, tenaculae, or wire inserted into or around the ribs of sternum has been used with satisfactory results. The administration of oxygen under positive pressure and the use of the Drinker respirator have been beneficial in decreasing paradoxical motion and improvement of ventilation.

One of the most interesting means of decreasing paradoxical motion of the chest wall is the use of tracheotomy as suggested by Carter and Giuseffi.² In the experience of these authors the simple procedure of tracheotomy reduces motion of the fractured ribs and provides an easy method of aspirating tracheobronchial secretions. The beneficial effects of tracheotomy are due to a reduction in volume of dead space in the respiratory tract and a decrease in resistance to inspired and expired air. By means of tracheotomy the dead space is reduced roughly from 150 cc. to 50 cc.; thus, the amount of tidal air available for alveolar ventilation is increased by 100 cc. This amount of increase becomes significant in severe crushing injuries of the chest in which the tidal air may be diminished from a normal volume of 500 cc. to as low as 320 cc. Reduction in resistance to inspiration and expiration by means of tracheotomy is reflected in the in-

tratracheal and intrapleural pressures. Carter and Giuseffi have observed that in both animals and man the intrapleural pressure changes are reduced roughly one half after tracheotomy. With the reduction of resistance to inspiration and expiration, paradoxical motion is minimized, subcutaneous emphysema is decreased, and pain is lessened.

Adequate tracheotomy care is mandatory, including cleansing of the inner tube, frequent aspiration, keeping in mind the patient's inability to cough effectively, and humidification of air by means of live steam or a good nebulizer. Oxygen under positive pressure may be supplied according to the method described by Jensen.³

Tension pneumothorax may develop rapidly, with or without fractures of the ribs. If physical examination of a patient in marked respiratory distress reveals the signs of pneumothorax, prompt relief of the tension should be obtained by the immediate insertion of a needle in the second interspace in the midclavicular line. Whether the pneumothorax is of the tension variety or not, the use of a catheter inserted through a trocar at the site of election and connected to a water-sealed system will more effectively promote rapid expansion of the lung and will insure against rapid reaccumulation of air. If air continues to bubble forcibly through the water-sealed system, a ruptured bronchus must be considered.⁴

Hemothorax should be treated by prompt, repeated aspiration or early catheter drainage. The site of election for drainage of blood or fluid is through either the eighth or ninth interspace in the posterior axillary line. In a patient with marked respiratory insufficiency the use of a catheter is preferred to repeated needle aspiration for rapid reexpansion of the lung. It has the additional advantage of permitting reasonably accurate measurement of blood loss while it occurs.

SUMMARY AND CONCLUSIONS

Severe injuries of the chest wall result in dangerous ventilatory insufficiency. Severe acute pulmonary edema may develop because of marked reduction in ventilation of both lungs, together with closure of the vascular bed surrounding the poorly ventilated bronchi and acute pulmonary hypertension. Minor injuries of the chest wall that do not produce an intolerable reduction in pulmonary ventilation require paravertebral block to relieve pain, frequent tracheobronchial aspirations to remove blood and secretions, oxygen to combat anoxic pulmonary edema, and occasionally adhesive strapping in an attempt to stabilize the chest wall.

Severe crushing injuries resulting in dangerous ventilatory insufficiency require elimination of paradoxical motion of the chest wall, maintenance of an adequate airway by repeated removal of tracheobronchial secretions and blood, and relief of pain. Tracheotomy, through its reduction in volume of dead space in the respiratory tract and the resulting decrease in intratracheal and intrapleural pressure variations, appears to increase alveolar ventilation, reduce paradoxical motion, relieve pain, and provide for repeated tracheobronchial aspirations.

Pleural complications of pneumothorax and hemothorax require closed drainage by a catheter inserted through a trocar or repeated aspiration by a needle.

EMERGENCIES OF THE LUNGS AND ESOPHAGUS

J. Gordon Scannell, M.D., Boston

Emergencies that involve the lung are usually serious, sometimes alarming, and always require prompt and intelligent treatment. The problem is one of a profound physiological disturbance—the patient cannot breathe, and the urgency of the situation is obvious. Here, as in other emergency situations, the thing not to do is to mask all symptoms by excessive medication, particularly with respiratory depressants and specifically morphine. Pain is rarely a serious problem, and panic, which is, can be controlled by barbiturate sedation plus a feeling of confidence in the attending doctor. This confidence will follow if the attending physician or surgeon knows what he is doing and does not feel that this knowledge is the special prerogative of the thoracic surgeon.

PNEUMOTHORAX AND HEMOTHORAX

As a practical matter, in dealing with trauma it is impossible to separate the problems of the lung from those of the chest wall and pleural space. The treatment of pneumothorax and hemothorax, however, is fundamentally the same whether associated with trauma or not. The objective of that treatment is the prompt reexpansion of the lung to obliterate the pleural space and to restore ventilatory function. The method of treatment is aspiration of the chest. This can be done most simply by needle aspiration, but, if the pneumothorax reaccumulates or if there is reason to think that it may, a small intercostal catheter can be inserted through a trocar under local anesthesia. This catheter should then be connected to some form of suction that should not exceed 20 to 25 cm. H₂O "negative" pressure and ordinarily should be at about -10 cm. H₂O.

Certain objections to prompt aspiration are frequently raised. The commonest of these is that rapid expansion may reopen the leak in the lung that led to the pneumothorax in the first place. This is theoretically possible. As a practical matter, however, it rarely, if ever, occurs so long as the degree of suction is kept within the physiological range mentioned. Furthermore, should the leak reopen after the lung is reexpanded, effective suction will maintain a negative intrapleural pressure and the lung will remain inflated. This situation is commonplace in the immediate postoperative period following many pulmonary resections.

A second objection is that the lung may be damaged as it reexpands against a sharp needle projecting into the pleural cavity. For this reason intercostal catheter drainage is to be preferred if more than one aspiration is needed or if it is necessary to maintain suction over any period of time. However, reasonable care in inserting a needle and withdrawal of that needle if contact with the expanding lung is felt should be enough to safeguard the lung from more than negligible damage. This objection is, therefore, a technical one as is the objection that infection may be introduced into an otherwise uncontaminated space.

Finally, strong objection is often raised to the prompt aspiration of a hemothorax. Here again the object of treatment is prompt expansion of the lung to fill the pleural space and to prevent its encasement by a constricting fibrin peel. Prompt aspiration is indicated, and the objection that by so doing one may reactivate bleeding is hardly valid for the following reasons. 1. If the bleeding is from the pulmonary circuit, this is low pressure bleeding, which once sealed off shows little tendency to start again. This observation can easily be verified in the operating room. 2. If the bleeding is arterial and from the chest wall or diaphragm, it is highly improbable that the changed intrathoracic dynamics due to aspiration will materially alter the bleeding situation. 3. If the hemorrhage is continuing, it is best to know this and to take active steps toward control.

There are, of course, certain practical modifications of the foregoing statements. Small pneumothoraces and small collections of blood need not be aspirated. By small I mean a pneumothorax in which the lung is separated from the chest wall by no more than an inch, or a collection of fluid is estimated to be less than 100 to 200 cc. As a rule a roentgenogram of the chest is taken before aspiration to confirm the diagnosis of pneumothorax and to define its extent. In the presence of any significant degree of respiratory distress, however, the delay necessary to secure a roentgenogram is dangerous.

Aspiration and/or closed drainage will generally effect reexpansion of the lung within 48 hours and is all that is indicated so long as a significant degree of expansion is promptly obtained. If only fair expansion is achieved and the patient fails to show steady improvement during the next few weeks, early exploratory thoracotomy is indicated for stoppage of the leak and expansion of the lung directly under vision. By thoracic surgical standards this procedure is not of great magnitude and is highly effective. It should certainly be done for a chronic pneumothorax or recurrent spontaneous pneumothoraces unless very definite contraindications exist.

There are two other surgical emergencies that involve the lung for which it is necessary to have some preformed plan of action. The first of these is severe hemoptysis; the second is major bronchial obstruction.

SEVERE HEMOPTYSIS

Sudden, severe hemoptysis is one of the most alarming things that can happen to a patient but fortunately, except as the terminal event of some severe illness, is very rarely fatal. Imparting this knowledge to the patient plus moderate sedation and strict rest are the first principles of treatment. It is important to remember that hem-

Assistant Surgeon, Massachusetts General Hospital, and Clinical Associate in Surgery, Harvard Medical School.

Read in the Panel on the Diagnosis and Treatment of Surgical Emergencies of the Chest before the joint meeting of the Section on Diseases of the Chest and the Section on General Practice at the 102nd Annual Session of the American Medical Association, New York, June 4, 1953.

orrhage of any great amount cannot remain concealed in the bronchial tree as it can in the gastrointestinal tract or in a body cavity. One therefore has the advantage of being constantly posted on how much bleeding is actually going on. There is, however, the disadvantage that hemorrhage from the lung can kill not only by exsanguination but also by drowning. Since this thought frequently occurs to the patient, the physician is under pressure to determine the cause of the bleeding and to localize its source. This is particularly true if the hemoptysis is large in amount or is a continuing one. Under these circumstances the need for emergency surgical intervention may arise, but, before this can even be considered, positive evidence must be had to lateralize the source of the bleeding. A chest roentgenogram may supply this evidence, particularly if it discloses a tumor mass, an abscess cavity, or localized bronchiectasis. Mere evidence of atelectasis is not enough, since collapse may be the result of aspiration of blood into any of the segmental bronchi. Bronchoscopy during the time of actual hemoptysis has a real place and should be more frequently used than it is. This procedure is ordinarily not difficult, except in the face of very active bleeding and in a high proportion of cases will yield the information desired, namely, from which lobe the bleeding comes. Bronchoscopy during a bleeding episode should not be attempted, however, unless facilities are available to proceed immediately with thoracotomy should serious bleeding be activated or a source of severe bleeding be found. The decision of when to operate in the presence of severe pulmonary hemorrhage requires the judgment and teamwork of physician, surgeon, and anesthetist.

BRONCHIAL OBSTRUCTION

Acute major bronchial obstruction by inhaled foreign body or by mucous plug is an emergency that is so well known that it hardly need be considered in detail here; however, there are one or two points that should be made. One of these is the difficulty of recognizing the emergency for what it is. For example, a child may have pneumonia that fails to respond promptly to one of the antibiotics. Only then may the history of an unobserved choking spell be elicited. Another very pertinent example is the child who, after a history of possible foreign body inhalation has an incomplete radiological examination that, because fluoroscopy or expiration films are omitted, fails to show evidence of trapped air. Every third year medical student knows that a foreign body in a bronchus may act as a ball valve, but it is surprising how one can forget this in practice, especially when the foreign body is not radiopaque.

The treatment of major bronchial obstruction is, of course, prompt removal of the obstructing agent before irreversible changes occur in the bronchus or the lung distal to the obstruction. A foreign body should be removed endoscopically if possible, by thoracotomy and bronchotomy if necessary. A mucous plug, which is a frequent cause of postoperative atelectasis, may require bronchoscopic aspiration if tracheal suction and measures designed to promote cough fail to dislodge it.

ESOPHAGEAL PERFORATION

Exclusive of bleeding varices, the common emergencies of the esophagus are obstruction and perforation in association with foreign bodies, acute chemical "burns," and instrumentation. Spontaneous perforation of the esophagus is known to occur but is uncommon, and in civilian life perforation of the esophagus from external trauma is rarely a surgical problem since it presupposes almost intolerable damage to the mediastinum.

Antibiotic therapy has produced a striking change in the management of esophageal perforation. This emergency may be divided into two distinct categories. The first is perforation with mediastinitis but without evidence of free communication with the pleural cavity. Surgical drainage is rarely necessary, but antibiotics in generous amounts and a nothing-by-mouth regimen for 48 to 72 hours will suffice. The mixed flora of the saliva including many anaerobic mouth organisms should be kept in mind in determining which antibiotics to use. Drainage is ordinarily required only if abscess formation occurs.

The second type of esophageal perforation is free perforation into a pleural cavity with an associated hydropneumothorax. Particularly in a crying child, this pneumothorax may assume dangerous proportions. The immediate treatment is aspiration of the chest and closed drainage. If facilities are available the logical treatment is then exploratory thoracotomy and suture of the perforation. If this is done within 24 hours, the mediastinal and esophageal tissues should be quite suitable for careful primary closure.

The same general policy should govern the management of "spontaneous" perforation of the esophagus. The difficult problem here is making the diagnosis. This emergency is generally, but not always, associated with severe vomiting and retching often after or during an alcoholic bout, or with known peptic ulcer disease. The clue to the diagnosis is the character of the pain, which is similar to that of a perforated ulcer in its onset and prostrating effect but with a substernal and pleuritic component. There is likely to be considerable abdominal rigidity, and the differential diagnosis may only be resolved by radiological examination.

CHEMICAL BURN

The acute chemical burn of the esophagus is a catastrophe that occurs to the child, to the would-be suicide, and occasionally to the student in the chemistry laboratory. The immediate treatment is the oral administration of a neutralizing agent, classically, weak vinegar for caustic alkalis, bicarbonate for acids, and soothing oils for both. During the acute phase the patient will tolerate nothing but liquids by mouth, and frequently these only in small amounts. One to two weeks after the accident is ordinarily the critical time in the management of esophageal burns. It is at this time that the weight of expert opinion favors the institution of a program of gentle bougienage that may extend over a period of months or years. The tragic consequences of an extensive esophageal stricture are well known.

CORTISONE THERAPY IN Rh INCOMPATIBILITIES

Oscar B. Hunter Jr., M.D., Washington, D. C.

In a preliminary article, the subject of cortisone therapy in Rh incompatibilities was first given recognition.¹ At that time, 12 cases had been studied in which it was evident that there might be some indication for the use of cortisone therapy in Rh incompatibilities. This concept was arrived at from observations in a large number of Rh incompatibilities. It was frequently noted that women with high Rh antibody titers delivered infants in relatively good condition, whereas some women with relatively low Rh antibody titers delivered infants that had severe erythroblastosis or even stillborn infants that died of the disease.²

The great variation in the disease, with patients having similar titers, led to the belief that there must be some other influencing feature beside the antibody titer. Further observations revealed that severe anemia developed in many erythroblastotic babies in the neonatal period, while in others very little anemia developed even though the infants were delivered of mothers with similar titers.

In acquired hemolytic disease of the adult, it has been observed that the use of cortisone and corticotropin (ACTH) tends to inhibit the hemolysis of the red blood cells affected.³ These red blood cells show the presence of antibodies on their surface as indicated by the positive direct Coombs' test. The similarity between this type of anemia and hemolytic disease of the newborn was apparent. Studies were initiated, therefore, to determine whether or not cortisone and corticotropin could possibly be effective in preventing erythroblastosis. In the initial study, the observations were limited to those on the newborn babies at the time of delivery. More recently studies have been directed to the baby in utero.

Previous studies on the involution of the adrenal cortex⁴ in the newborn led to the consideration that delivery was of prime importance in this phenomenon, because it removed the baby from the influences of corticotropin in utero. This involution of the newborn's adrenal cortex has been consistently observed. It is concurrent with hemolysis of the red blood cells. Proof of the correlation of hemolysis of the red blood cells in a baby with a positive Coombs' test with the adrenal cortical involution was then of foremost consideration.

From other observations in our laboratory, poor placental development has resulted in poor pregnanediol excretion. This would be the end-result in fetal hemolytic anemia, and, therefore, the quantitative estimation of this hormone should be a source of guidance as to the condition of the blood of the fetus in utero. The estimation of both pregnanediol and 17-ketosteroid excretion rates was thought to be of value in estimating the fetal adrenal cortical function as well as the placental function. Progressive anemia in utero would be identified again by the fall of the excretion levels and vice versa. The hematological status of the fetus would thus be reflected.

Observations were made on mothers with Rh incompatibilities treated with cortisone. The dosage of corti-

sone was controlled by the studies of these hormones, in an effort to reduce the problem to scientific measurement rather than to vague clinical judgment.

MATERIAL AND METHODS

This study consists of the observations made on 67 women with antibody titers considered to be sufficiently high to produce erythroblastosis. All maternal titers were 1:8 or higher. The mothers usually had a history of the delivery of previous severely erythroblastotic babies. These women all received cortisone or corticotropin, and, during the period of observation, a large percentage of the mothers were studied by means of 17-ketosteroid and pregnanediol studies on the urine excreted during 24 hour test periods. These studies were made at weekly or semimonthly intervals, and they were started around the 20th week and continued until delivery. The 17-ketosteroids were estimated by means of Zimmermann's test⁵ and the pregnanediol by the Chaney-Fischer technique.⁶ Cortisone was given in doses of 100 mg. per day, 25 mg. every six hours, and where indicated the dose was increased to 150 mg., or 25 mg. every four hours day and night. If necessary, 200 mg. per day was given. The usual symptoms of mild sodium and fluid retention were occasionally observed in these women.

REPORT OF CASES

CASE 1.—This 23-year-old white woman had previously had an Rh-positive infant that died in the neonatal period from severe erythroblastosis. The present pregnancy progressed normally, and in figure 1 there is a diagram of the 17-ketosteroid and pregnanediol excretion studies made on this patient. There was a slight rise in the blocking antibody titer to 1:512 during the course of the pregnancy. The 17-ketosteroid and pregnanediol excretion rose gradually in a gentle slope during the course of the pregnancy that was finally terminated at the end of 38 weeks by cesarean section, because of a previous section. The patient exhibited edema in the last several weeks. The child was Rh negative and in perfect condition.

CASE 2.—A 28-year-old white woman had been sensitized as a result of transfusions in the past. Her first pregnancy terminated in a stillbirth after a cesarean section at seven months. Her blocking antibody titer during this pregnancy rose to 1:256. The 17-ketosteroid and pregnanediol excretion showed some tendency to improve when the patient was given 100

From Georgetown University School of Medicine and the Doctors Hospital Research Foundation.

The cortisone used in this study was provided by Dr. Elmer Alpert of Merck and Company, Rahway, N. J., and the ACTHargel by Dr. Richard J. Meyers of the Armour Laboratories, Chicago.

Members of the staff of the Oscar B. Hunter Memorial Laboratory and the Blood Grouping Laboratory, Washington, D. C., assisted in the preparation of the charts and manuscripts and in the performance of the tests.

mg. of cortisone at the 21st week (fig. 2). In the 23rd week, however, the 17-ketosteroid level showed a tendency to fall and at the 25th week both the 17-ketosteroid and pregnanediol excretion showed a tendency to diminish. When these observations were made, the fetus was believed to have died, the 26th week. At that time no increase in dosage of cortisone was made. This case illustrates an inadequate cortisone dosage for this particular patient.

Fig. 1.—Graph showing pregnanediol (broken line) and 17-ketosteroid (solid line) excretion of normal patient receiving cortisone and corticotropin gel. Patient delivered a normal Rh-negative baby.

CASE 3.—This 32-year-old woman had had three previous pregnancies. The first child was slightly jaundiced at birth. The second baby was delivered three weeks prior to term and, in spite of repeated small transfusions, died six days after birth. The third pregnancy was terminated in an abortion at six weeks. During the present pregnancy, the patient's antibody titer rose from 1:64 to 1:512. She was given cortisone, 100 mg. daily, at the 32nd week of pregnancy and was followed with pregnanediol and 17-ketosteroid studies from that time until delivery (fig. 3). In addition to cortisone, the patient was given a 20 mg. injection of corticotropin gel on July 14 and Aug. 5. She delivered an Rh-positive baby in good condition on Aug. 17. The baby was given an exchange transfusion, and thereafter its course was uneventful.

Fig. 2.—Graph showing pregnanediol (broken line) and 17-ketosteroid (solid line) excretion in patient whose baby was Rh positive and died of erythroblastosis. Cortisone dosage was inadequate.

CASE 4.—The husband of this 24-year-old, Rh-negative, white woman was homozygous for the Rh factor. In the past she had one normal child, and a second child died at three days, although an exchange transfusion was performed. The third child was born anemic, was given a transfusion, and survived. During the fourth pregnancy, there was a definitely

higher antibody titer (1:128). The prognosis was considered poor. During this pregnancy, the patient was followed with 17-ketosteroid and pregnanediol estimations, and as shown in figure 4, administration of cortisone was started at approximately the 32nd week because of the continued fall in levels. The cortisone dose administered was 100 mg. per day, 25 mg. every six hours. A rise in the 17-ketosteroid and pregnanediol levels was not observed, and consequently one week later the cortisone dosage was increased from 100 to 150 mg., 25 mg. every four hours. The patient continued to receive this dose until the 38th week at which time she was delivered by medical induction of labor. The 17-ketosteroid and pregnanediol levels were slightly lower than usual, but the early delivery was suggested in order to salvage a viable fetus. The child was delivered in excellent condition without signs of erythroblastosis. Transfusion was performed subsequently without complications. This case illustrates the advantage of 17-ketosteroid and pregnanediol estimations in controlling the dosage of the drug in order to insure that an adequate quantity of the drug is being administered to the patient.

Fig. 3.—Graph showing pregnanediol (broken line) and 17-ketosteroid (solid line) excretion in patient receiving cortisone and corticotropin gel. Patient delivered an Rh-positive infant in good condition. Dosage was adequate.

Table 1 illustrates the results of the entire series of cases. From this table it can be seen that the fetal mortality rate was considerably reduced by the use of cortisone. Of particular importance is the high salvage rate of infants born of mothers who have previously had still-

TABLE 1.—Results of Cortisone Therapy on Erythroblastosis

Result of Previous Pregnancy	Result of Pregnancy During Which Cortisone Was Administered		
	Infant Lived	Infant Born Alive	Infant Stillborn
Normal infants	23 (95%)	1	..
Erythroblastic infants	14 (93%)	1	..
Miscarriages	4 (57%)	..	3
Infants stillborn or died.....	15 (71%)	3	3
Total.....	56 (84%)*	5	6

* Including 9 Rh-negative infants.

births or neonatal deaths. Of these severely affected, there still remains a small percentage of infants (16%) who will die either in utero or in the neonatal state in spite of cortisone therapy. The administration of cortisone reduced the 17% of stillbirths and 10% of deaths not salvageable by exchange transfusion.

Table 2 is an outline of the histories of all mothers who had babies dying as the result of erythroblastosis in a previous pregnancy and the results of a subsequent pregnancy during which cortisone was given in the last trimester. It is important to observe that, prior to the use of cortisone, we had never seen an Rh-positive child born alive of a mother who had previously had a stillbirth.

COMMENT

From these observations, it is evident that pregnanediol and 17-ketosteroid estimations on 24 hour urine specimens give considerable information as to the status of the fetus in utero. It is believed that they reflect placental and fetal adrenal cortical function. These observations, when considered in the light of the Rh antibody titers of the patients, enable the observer to determine when the infants are embarrassed in utero. With anemia there is a fall in the hormone excretion levels. We have been successful in predicting the death of the babies by this fall. In some instances, however, we have been led astray by a hydropic placenta that produces a high pregnanediol content, but on reconsideration the fall of 17-

Fig. 4.—Graph showing pregnanediol (broken line) and 17-ketosteroid (solid line) excretion in patient receiving cortisone. Dosage at first, 100 mg. per day, was inadequate.

ketosteroid excretion should have given some indication of the poor status of the infant. With these chemical observations, it is possible to regulate the dosage of cortisone given to the mother. The cortisone administered must be transmitted to the child in order to inhibit the hemolytic activity. There has been associated clinical, as well as laboratory, evidence of improvement of the fetus. Fetal improvement has been observed by the mother and obstetrician correlating with use of the 17-ketosteroid and pregnanediol excretion levels observed in the laboratory. Cases 14 and 15 in table 2 are typical examples of this. Both activity and fetal heart tones improved with therapy.

There still remains a small percentage of infants (16%) who will die in utero or in the neonatal state. Cortisone therapy will reduce by 71% the 17% of stillbirths and the 10% of deaths not preventable by exchange transfusion.

In table 2, it should be noted that two of the three women who had stillbirths were treated with cortisone for less than two weeks. Two of the three infants that were born alive and later died were born of mothers whose previous infants were stillborn. Both babies were severely

erythroblastic. Both showed considerable clinical improvement while receiving therapy, but both were delivered prior to the expected date when larger doses of cortisone were to have been given. Further analysis of table 2 contrasts strikingly the change in outcome associated with cortisone therapy. Seven out of eight babies survived after cortisone therapy, whereas their siblings had died in the neonatal period. Two of these were Rh negative. Thirteen patients with a history of previous stillbirth subsequently delivered 10 live babies, 2 of which died in the neonatal period. Only one survivor was Rh negative. The relatively high red blood cell counts noted were encouraging, and, even when the count was as low as 3 million per cubic millimeter, the babies appeared in excellent condition.

* Infant received exchange transfusion.

The exact nature of the method of function of cortisone is not entirely clear. In these cases, the results of the Coombs' test on the newborn infant is positive if the child is Rh positive. This, therefore, indicates that, in spite of the cortisone, a union of antigen and antibody has occurred, but, unlike the usual condition, the antigen-antibody complex does not result in hemolysis. Theoretically, perhaps, there is an inhibition by the corticoids of the hemolytic mechanism blocking the action of complement. This is entirely theoretical, and we have not been able to make observations to prove that this particular hypothesis is either true or false.

There appeared to be variables other than adrenal cortical function, since a few infants died in spite of the cortisone therapy. It nevertheless seems to be a valid conclusion that the cortisone does have a very definite effect

in the great majority of cases. The dosage of cortisone usually used has been 25 mg. every six hours. This dosage should be begun either before the death of the fetus, as predictable by previous pregnancies, or when there is some evidence of fall in the 17-ketosteroid and pregnanediol excretion. This latter method is much more accurate and much more effective and is the only method we have used in the last 30 cases. We initially observed the 17-ketosteroid and pregnanediol levels around 20 weeks and followed this level at semimonthly intervals until there was some indication of fall or until the 24th week. Thereafter, these levels were observed weekly, and, if there was a poor progression, cortisone therapy was initiated. If, during cortisone therapy, either the 17-ketosteroid or the pregnanediol excretion tends to fall or does not continue to rise, an increase in dosage is initiated; namely, 150 mg. a day or 25 mg. every four hours, day and night. This latter dose seems to be a satisfactory one for almost all patients. Occasionally, 200 mg. may be necessary.

Toxic effects other than edema were minimal. Every patient required restriction of sodium. Once it was necessary to hospitalize the mother because of polyhydramnios before initiating cortisone therapy. Growth of hair and striae were exaggerated by the treatment in a few instances. One mother had an acneform eruption on the

chest when the cortisone dosage was increased to 150 mg. daily. This disappeared when the dosage was reduced to 100 mg. No psychosis or undue depression was noted, in fact, most women felt improved while receiving the therapy. In the newborn, there is occasionally an increase in fluids as evidenced by the weight loss in the first few days. This has never constituted an unusually difficult problem.

SUMMARY

The normal rise of 17-ketosteroid and pregnanediol levels in the urine during pregnancy may be used as a means of following the course of the fetus of the Rh-negative mother with a high antibody titer. Administration of cortisone should be started when the normal progression of these hormones falters. Twenty-five milligrams of cortisone every six hours is sufficient dosage at the start. The dosage may be increased if the hormone level does not continue to rise. The newborn child may be expected to lose a small amount of weight. An exchange transfusion is usually necessary to complete the therapy of the newborn infant. This therapy reduced the mortality rate of babies born alive from 10%, with exchange transfusion alone, to 3%. The incidence of stillbirths was reduced from 17% to 5%.

IMPROVED FERTILITY AND PREVENTION OF ABORTION AFTER NUTRITIONAL-HORMONAL THERAPY

S. J. Glass, M.D.

and

M. L. Lazarus, M.D., Beverly Hills, Calif.

The causes of functional infertility are obscure and elusive. Those of abnormal pregnancy and habitual abortion are no less so. Many factors of nutritional and endocrine significance may be involved, but thus far these have been loosely defined and so remain in a rather confused state.

We postulate that many cases of functional infertility and abortion may result from errors in sex hormone metabolism associated with variable degrees of nutritional and hepatic insufficiency. This concept is based on abundant evidence from investigators in the field of nutrition¹ and from workers investigating the influence of the liver on sex endocrine function.² Previous observations clearly

relate liver damage with gonadal damage.* These clinical and experimental data tend to support the idea that liver-gonadal syndromes may be associated with infertility. Hepatic insufficiency is frequently the cause of the following sex organ changes: in men, testicular damage, gynecomastia, impotence, and infertility; in women, ovarian dysfunction, menstrual disorders, cyclomastopathy, and infertility.

Good nutrition and normal liver function are synonymous. Deficiency of either one is usually followed by some reciprocal effect on the other. Likewise any significant chronic deficiency of nutrition and/or liver function reflects unfavorably on reproductive physiology. These nutritional-liver-hormonal inter-relationships are in harmony with the postulate of the interdependence of enzymes, hormones, and vitamins as expressed by Harrow⁴: "These are not separate entities, each going its own way, but all three are intimately related to one another with a cooperative plan so delicately handled together that a failure of any one of them to act immediately upsets the dynamic equilibrium of the body as a whole, resulting in pathological symptoms or disease." It is difficult to prove whether minor and subclinical nutritional and hepatic deficiencies of long duration depress fertility, because of insensitive laboratory tests for the detection of such deficiencies. Histories of dietary intake by patients are no-

S.: Relations Between Fertility and Nutrition: Normal Reproductive Performance of Rats, *J. Metab. Research* 3: 201-231, 1923; Production of Sterility with Nutritional Regimes Adequate for Growth and Its Cure with Other Foodstuffs, *ibid.* 3: 233-316, 1923.

toriously unreliable, especially those obtained from clinic populations. Since a substantial number of our patients are former inmates of Nazi concentration camps, however, malnutrition was a conspicuous feature of their past history. Moreover, a minority of our subjects showed abnormal or borderline abnormal results of liver function tests.

Biskind,⁶ among many others, believes that suboptimal as well as frank nutritional deficiency is more widespread than is commonly suspected or diagnosed. More critical clinical study including dietary inventory and tests of liver function must be carried out on every infertile couple to reveal these potential deficiency factors. The nutritional regimen proposed here is designed to provide a superabundance of protein, liver, and naturally occurring vitamin B complex foods; it is designed to enhance liver function as well as the over-all nutritional state.

Our nutritional regimen provides the broadest spectrum of foods rich in protein and B complex value. Because each supplement contains some substances, known and unknown, not contained in the other, the sum total of these foods provides infinitely more real value than synthetic mixtures, again emphasizing that the "whole is greater than the sum of its parts." Long-term use of this nutritional regimen seems necessary to overcome what appears to be a refractory state of the reproductive system in many cases of functional infertility.

In our opinion preliminary nutritional improvement constitutes a necessary prerequisite for use of sex hormone supplements. It is analogous to fertilizing the soil prior to the planting of seeds on the logical assumption that such a fertilized soil will, so to speak, produce better crops or improved gametogenesis in infertile subjects. If such a regimen is essential to stabilize sex hormone metabolism in infertile patients, it is even more important to those who achieved pregnancy, especially women who have experienced abortion or miscarriage.

METHOD

A group including 22 men and 50 women was studied according to the minimal standards laid down by the American Society for the Study of Sterility. In addition, a battery of liver function tests were routinely carried out.* Of the 50 infertile women, 34 were nulliparous and 6 had become infertile for a variable number of years after having from one to three children. Of 10 who had aborted two or more consecutive pregnancies, 4 had become infertile. The duration of infertility in these 50 women varied from 2 to 16 years. Endometrial premenstrual biopsy specimens were proliferative in 4 patients and mixed or hypoplastic in 33 patients. Endocervicitis was present in 5 women, and 14 had impaired or borderline abnormal liver function.

These patients were then provided with an optimum dietary including food supplements of the following specifications: (1) optimal caloric intake (designed to reduce weight if necessary), (2) protein content of 1.5 to 2 gm. per kilogram of body weight, (3) vitamin A content of 25,000 to 50,000 units, and (4) foods rich in protein and vitamin B complex, such as liver (edible, or desiccated whole liver), 30 cc. of rice bran extract (Galen B), 60 to 90 gm. of brewer's yeast flakes, and 30 to 60 gm. of wheat

germ. To insure the patient's long-term cooperation, palatable recipes should be provided for his use. To further enrich the diet in urgent cases or to provide a temporary substitute for the crude supplements that may not be well tolerated by some patients special capsules are being prescribed. These capsules incorporate concentrates of brewer's yeast, whole liver, vitamins A and B complex, and mixed tocopherols in a ratio that is roughly analogous to the crude supplements. After 30 to 60 days of this nutritional regimen, sex hormones were prescribed in the following schedules: 1. Men were provided with testosterone propionate, 50 mg. intramuscularly every other day until a total of 500 mg. was given. 2. Women were provided with oral estrogen and buccal progesterone therapy in the following schedule: estrogen, 0.25 to 2.5 mg. daily during days 5 to 25 of the menstrual cycle, and progesterone, 20 to 40 mg. daily during days 15 to 25 of the cycle. This was usually continued for from 3 to 6 cycles with decreasing estrogen dosage and after a lapse of one or 2 cycles was resumed for another trial period of from three to six months if necessary. 3. Women who had aborted repeatedly or who had become infertile after having one or more children were pro-

vided with the same combined regimen as the nulliparous subjects for a variable number of months before pregnancy was achieved. During their pregnancy progesterone was prescribed in doses of 100 mg. of macrocrystals intramuscularly every 5 to 10 days, or 125 mg. in oil intramuscularly every other day. When injections could not be taken, buccal tablets of progesterone in doses of 40 to 60 mg. daily were substituted.

RESULTS

Fertility, with resultant pregnancy, was restored to 19 of 34 nulliparous women and also to 4 of 6 infertile multiparous women (table 1). Four of these 23 subjects

* The liver function tests were usually determination of sulfobromophthalein (Bromsulphalein) secretion, cephalin flocculation, thymol turbidity, and glycogen storage (Kinsell).

aborted the pregnancy. Of the 10 women who had experienced two or more consecutive abortions, 8 had normal babies. Of the 22 sterile men, 15 experienced improved spermatogenesis followed by pregnancy in 10 wives, one of whom aborted (table 2). No pregnancy followed treatment of the five men with testicular atrophy. The favorable results were attained in variable periods of time, ranging from 4 to 22 months with an average of over 9 months in both sexes. Significantly, most of the patients experienced marked improvement in general health in addition to improved fertility.

COMMENT

Chance expectation may well account for some of the favorable results, but in our previous experience with hormonal therapy alone few cures were obtained. Moreover, with the chi-square method of comparison the results obtained with the combined nutritional and hormonal therapy with those obtained after hormonal therapy alone, it is apparent in tables 1 and 2 that significantly

better responses followed the combined regimen. Thus it is seen that the number of pregnancies achieved by the women in group A is higher than that in group B ($t = 3.32$). Likewise the number of pregnancies that followed the combined therapy in the men of group A was significantly higher than that which followed either gonadotropic (group C) or testosterone (group D) therapy exclusively ($t = 3.38$). The favorable responses that follow the combined treatment suggest that our "total push" regimen is a more logical approach to the problem of infertility.

Though much of the regimen may be empirical, the treatment does anticipate the need for optimum levels of nutritional and hormonal substances essential to fertility. It is suggested that prolonged saturation with the beneficial food supplements, inherent in the nutritional regimen, renders the entire reproductive system more responsive to endogenous as well as exogenous sex hormones so that gametogenesis progresses to full and efficient maturation. What may be lacking in many cases of functional infertility are the factors that stimulate the final phase of spermatogenesis and ovulation.

Study of the majority of our patients usually revealed, as do most other studies, not outright failure of gametogenesis, but rather less serious degrees of failure as shown

by (a) spermatogenic arrest or hypospermatogenesis and (b) premenstrual endometrium of mixed or hypoplastic secretory character. Such functional deficiencies suggest that there is inadequate stimulation or that unknown factors are lacking for the efficient completion of the cycle of gametogenesis. The favorable responses observed in this study suggest that the abundant nutritional regimen together with the supplements of sex hormones provide the added stimulus essential to normal gametogenesis and normal fertility. These results warrant further trials with the combined nutritional and hormonal therapy by all interested clinical investigators, at least until better or more specific treatment becomes available.

SUMMARY AND CONCLUSIONS

A combined nutritional and hormonal regimen was applied in the management of 22 men and 50 infertile women. No apparent organic basis was evident in the sex organs. A minority of the patients had a history of malnutrition and manifested some impairment of liver function. After an average of nine months of treatment, 19 of the 34 nulliparous women achieved pregnancy, 2 of whom aborted. Of the six infertile women who had borne one or more children four attained pregnancy again but one of these aborted. Of the 10 who had aborted previously, 8 achieved normal full-term pregnancy.

Of the 17 men with moderately severe oligospermia, 15 had improved spermatogenesis followed by pregnancy in 10 of their wives, one of whom aborted. Of five men with severe oligospermia associated with testicular atrophy, only two showed some improvement in spermatogenesis without pregnancy in their wives. These favorable results are better than those of chance expectation or those obtained with nutritional or hormonal therapy alone. It is suggested that the combined regimen proposed here provided the added stimulus essential to normal fertility.

360 N. Bedford Dr. (Dr. Glass).

Proteolytic Enzymes.—Streptokinase-streptodornase and crystalline trypsin are extremely valuable adjuncts in the management of . . . wounds complicated by necrosis and infection. Their use is not a substitute for surgical débridement. Whenever foreign material is contained within a wound, cure should not be anticipated until the foreign material is removed. . . . Osteomyelitis involving cancellous bone primarily is improved, or arrested temporarily, but relapses occur frequently because of inability to obtain contact of the enzymes with the multiple localized abscesses prone to develop in cancellous bone. Streptokinase-streptodornase appears to produce better results than trypsin in deep-seated wounds with multiple sinuses. Streptokinase-streptodornase administered in fresh operative wounds causes continued mild bleeding. The authors have not found this a cause for concern. Trypsin acts more rapidly and is more effective in surface wounds. Both streptodornase-streptokinase and trypsin are of practical benefit because of their ability to digest necrotic tissue, thereby cleaning wounds, and making less favorable media for the growth of bacteria. In some instances enzymatic débridement alone has been sufficient for healing. In others it has cleaned the wounds preparatory to definitive surgical intervention. These agents have not been observed to affect living tissue except by causing skin irritation.—Col. A. W. Spittler and R. E. Parmenter, *The Use of Proteolytic Enzymes in War Wounds*, *The Journal of the International College of Surgeons*, January, 1954.

CLINICAL NOTES

TREATMENT OF HERPES ZOSTER WITH CORTISONE

Maxwell L. Gelfand, M.D., New York

The demonstration by Hench and his co-workers¹ in 1949 that cortisone exerts a dramatic effect on rheumatoid arthritis marked the beginning of a new approach in the field of therapeutics. At first, it was thought that this steroid, as well as corticotropin (ACTH), was specific for a certain group of conditions, but it soon became apparent that these hormones exerted an effect on a number of disparate diseases. A considerable amount of experimental evidence has accumulated to indicate that these drugs have a widespread action, influencing the metabolic and physiological function of many tissues and organs. Their clinical applicability would therefore seem to be inexhaustible, and the list of diseases for which they are being employed continues to grow. Although steroid therapy has been used in the ocular complications following herpes zoster ophthalmicus,² there has been no report concerning the effect of cortisone on herpes zoster, hence this preliminary report.

METHOD OF TREATMENT

Five patients, four women and one man, ranging in ages from 32 to 72 years, with severe acute herpes zoster were treated with cortisone administered orally. They were given 200 mg. the first day in four divided doses, followed by 100 mg. daily for seven days. Thereafter the

TABLE 1.—Condition of Patients with Herpes Zoster Before Cortisone Therapy*

dose was reduced to 25 mg. twice daily for four days. In addition, the two patients with ophthalmic involvement received cortisone administered locally by instillation. The classic symptoms of shingles were present in all patients: the triad of systemic manifestations of a general infective disorder, typical radicular pain, and character-

istic herpetic lesions. In two patients the eruptions were distributed unilaterally over the thoracic region, in one the lumbar and sciatic area was affected, and in two patients the supra-orbital site showed these lesions. Except for a slight hypertensive condition in one patient, none of the contraindications to the use of cortisone, such as diabetes, latent tuberculosis, a previous major psychotic episode, congestive heart failure, recent occurrence of thromboembolism, a deep-seated pyogenic infection, or an urgent need of surgical treatment, were present. All

30	7th day	Rebound effect	

* None of these patients had any side-effects from cortisone.

patients were observed twice weekly in order to evaluate the degree of improvement in each and to detect any signs of undesirable side-effects from prolonged therapy with cortisone.

RESULTS OF TREATMENT

Dramatic relief of pain occurred within 24 to 36 hours in four of the five subjects treated. The patient with chronic lymphatic leukemia failed to respond to therapy. The skin eruption did not progress in any of the patients nor were there any evidences of secondary infection. The course of healing of the superficial lesions continued in the usual manner, requiring from one to three weeks. The uveitis and conjunctivitis that characterized the ophthalmic form of herpes zoster cleared rapidly in one patient, but the improvement was somewhat less spectacular in the patient who had leukemia (table 2). In one instance, pain returned one week after cessation of treatment. However, upon reinstitution of therapy with 100 mg. of cortisone, in four divided doses daily for one week, the pain was permanently abolished. No complications or sequelae were observed unless the relapse mentioned could be considered as an instance of post-herpetic neuralgia. This is very unlikely, since the condition cleared so quickly after an additional week of cortisone therapy. As a rule, post-herpetic neuralgia continues for a very long time and is extremely painful. This manifestation should be regarded as a rebound phenomenon not infrequently seen in steroid therapy. Despite the extensive and severe involvement, all patients felt so well that they were able to continue their usual work. None of the usual signs of undesirable metabolic or physiological disturbances, such as a gain in weight, glycosuria, alkalosis (as measured by the carbon dioxide content of the blood), or hypopotassemia (as seen in the electrocardiogram), were present.

COMMENT

Herpes zoster, commonly known as shingles, is an acute infectious disease of viral origin affecting the nervous system and manifested by secondary cutaneous changes. Although the condition is essentially benign and

1. Hench, P. S.; Kendall, E. C.; Slocumb, C. H., and Polley, H. F.: Effect of Hormone of Adrenal Cortex (17-Hydroxy-11-Dehydrocorticosterone: Compound E) and of Pituitary Adrenocorticotrophic Hormone on Rheumatoid Arthritis: Preliminary Report, Proc. Staff Meet., Mayo Clin. 24: 181, 1949.

followed by spontaneous recovery, it carries with it a high degree of morbidity in the elderly age group. In addition, complications have been observed, some of which are irreversible. Post-herpetic neuralgia, the most frequent and rather common aftereffect, is particularly distressing. Encephalitis, a rare sequela, may prove fatal, while in the ophthalmic variety loss of vision is far from uncommon. Paralysis of the upper as well as lower motor neurons is also a complication occasionally observed in this disease.

There is no specific treatment for herpes zoster or any of its complications. Innumerable remedies have been suggested, and, at different times, a variety of agents have enjoyed popularity. The use of analgesics and vaccines, injections of procaine, x-ray radiation and administration of thiamine hydrochloride (both orally and parenterally), vitamin B₁₂, Protamide (colloidal solution of a proteolytic enzyme), and the newer antibiotics (chlortetracycline [Aureomycin] and chloramphenicol) have all had their proponents. In the older group of patients with extensive involvement, however, all these modalities of treatment have been found wanting for the adequate relief of the excruciating pain experienced by patients in the acute stage of the disease and of the discomfort caused by the post-herpetic neuralgia or other sequelae.

The mechanism by which cortisone exerts its beneficial effect is by no means well known. The drug alters in some mysterious way certain reactions of the tissues to adverse stimuli. While it is incapable of destroying pathogenic organisms or directly influencing toxins, allergens, or other noxious agents, it definitely can suppress inflammation, whether allergic, infectious, or nonspecific in origin. This latter property, however, may be contraindicated in some instances. Under conditions in which the inflammation is detrimental to the body, the administration of cortisone results in improvement, whereas under circumstances in which the inflammatory process represents a participation in the body's defense against micro-organisms, harm results from its use. Cortisone itself exerts no curative action but, when used in responsive conditions that are naturally self-limited, it may check the pathological process while the disease runs its course.

A number of infections of either bacterial, viral, or parasitic origin have shown considerable clinical improvement when cortisone is employed, either alone or in conjunction with antibiotics. Smadel, Ley, and Diercks⁴ administered cortisone in addition to chloramphenicol to eight patients with typhoid. They found a more marked amelioration of the acute symptoms after

therapy with the combination than after the administration of the antibiotic alone. Woodward and his co-workers⁵ treated seven typhoid patients with cortisone alone and found that in six patients a marked defervescence occurred while the condition remained unchanged in the seventh. Numerous authors have reported considerable success in the treatment of ulcerative colitis with cortisone. Reeder and Mackey⁶ noted a favorable response in several cases of bacterial pneumonia treated with cortisone administered by nebulization. The Waterhouse-Friderichsen syndrome, often seen in fulminating meningococcemia, has shown a dramatic response when cortisone is added to other medicaments used in treatment. Boling and his associates⁷ have given cortisone in conjunction with appropriate chemotherapy to six patients with severe peritonitis, and in all patients an immediate reduction or disappearance of signs of systemic toxicity was noted. Michael⁸ administered cortisone to seven patients with mumps orchitis and found that the pain and fever disappeared more rapidly than was expected. Trichinosis was also favorably influenced when treated with cortisone. The toxicity and clinical course of Rocky Mountain spotted fever were more markedly alleviated by a combination of cortisone and chloramphenicol than by the antibiotic alone.⁹ Thus there is sufficient proof to indicate that cortisone has a place in the treatment of acute infectious diseases.

The favorable response noted above in four of five patients with severe herpes zoster treated with cortisone has real significance despite the fact that this is but a small group. The majority of those treated were between 50 and 70 years of age, and in addition the condition of two patients was complicated by ophthalmic involvement. It is well known that the effect of herpes zoster in the aged is considerably severer than in the young and that the incidence of complications is much higher in the former group. When the virus attacks the eye, loss of vision is not uncommon. It is quite possible that the local instillation of cortisone supplementing the oral route of administration was of some value in obviating serious ocular damage. In the patient with chronic lymphatic leukemia and herpes zoster ophthalmicus, who did not respond systemically to cortisone, some improvement was evident in the uveitis and conjunctivitis. Thus, the preservation of sight in both instances may well have been due to the use of cortisone.

It is well known that cortisone can mask the development of a new infection and prevent the detection of its progress by suppressing the cardinal signs and symptoms. This property has been offered by many as an argument against the use of the drug in serious infections. However, when short courses of steroid therapy are employed and the patient is carefully supervised with constant attention to the signs in the abdomen and chest, checked frequently by fluoroscopic examinations, such concealment can be avoided. Thus it appears that a brief course of cortisone therapy is useful in the treatment of severe and extensive herpes zoster since it shortens the acute phase, diminishes the intense pain, and reduces the incidence of complications. It should be reserved for patients in the older age group and those failing to respond to the conventional method.

Phosphorus.....	186
Iron.....	8

Calories.—0.98 per gram; 27.8 per ounce.

Use.—In the feeding of infants, convalescents, and others requiring a soft diet.

The following products containing non-nutritive artificial sweeteners intended for use in low carbohydrate, low sodium, and other therapeutic diets have been accepted as conforming to the rules of the Council. Data regarding composition represent the best available information. The company has agreed to make continuing analytical studies, especially of the sodium content, in order to make available information concerning the extent of natural variations in composition.

Richmond-Chase Company, San Jose, Calif.

Diet-Delight Brand Special Dietetic Pack Apricots, Halves, Unpeeled

This product consists of apricots, Blenheim variety, packed in water with addition of cyclamate sodium (Sucaryl).

Analysis (submitted by manufacturer).—Total solids 9.6%, moisture 90.4%, ash 0.4%, fat 0.05%, protein 0.5%, available carbohydrates (total sugar as invert) 5.4%, carbohydrates (by difference) 8.2%, crude fiber 0.4%, sodium 4.0 mg./100 gm., and cyclamate sodium (Sucaryl) 0.08%.

Calories.—0.24 per gram; 6.8 per ounce.

Use.—In low calorie, low sodium, and other therapeutic diets.

Diet-Delight Brand Special Dietetic Pack Royal Anne Cherries

This product consists of Royal Anne Cherries packed in water with the addition of cyclamate sodium (Sucaryl).

Analysis (submitted by manufacturer).—Total solids 12.5%, moisture 87.5%, ash 0.4%, fat 0.05%, protein 0.7%, available carbohydrates (total sugar as invert) 8.4%, carbohydrates (by difference) 11.1%, crude fiber 0.2%, sodium 4.0 mg./100 gm., and cyclamate sodium (Sucaryl) 0.07%.

Calories.—0.37 per gram; 10.5 per ounce.

Use.—In low calorie, low sodium, and other therapeutic diets.

Diet-Delight Brand Special Dietetic Pack Kadota Figs

This product consists of Kadota Figs packed in water with the addition of cyclamate sodium (Sucaryl).

Analysis (submitted by manufacturer).—Total solids 14.0%, moisture 86.0%, ash 0.3%, fat 0.2%, protein 0.6%, available carbohydrates (total sugar as invert) 12.4%, crude fibers 0.6%, sodium 4.0 mg./100 gm., and cyclamate sodium (Sucaryl) 0.07%.

Calories.—0.56 per gram; 15.9 per ounce.

Use.—In low calorie, low sodium, and other therapeutic diets.

Diet-Delight Brand Special Dietetic Pack Fruit Cocktail

This product consists of peaches, pears, grapes, pineapple, and artificially flavored and colored cherries (Maraschino type), packed in water with the addition of cyclamate sodium (Sucaryl).

Analysis (submitted by manufacturer).—Total solids 10.1%, moisture 89.9%, ash 0.2%, fat 0.06%, protein 0.4%, available carbohydrates (total sugar as invert) 6.7%, carbohydrates (by difference) 9.0%, crude fiber 0.4%, sodium 4.0 mg./100 gm., and cyclamate sodium (Sucaryl) 0.07%.

Calories.—0.29 per gram; 8.3 per ounce.

Use.—In low calorie, low sodium, and other therapeutic diets.

Diet-Delight Brand Special Dietetic Pack Yellow Cling Peaches (Halves)

This product consists of peaches packed in water with the addition of cyclamate sodium (Sucaryl).

Analysis (submitted by manufacturer).—Total solids 8.5%, moisture 91.5%, ash 0.3%, fat 0.02%, protein 0.4%, available carbohydrates (total sugar as invert) 5.2%, carbohydrates (by difference) 7.6%, crude fiber 0.2%, sodium 4.0 mg./100 gm., and cyclamate sodium (Sucaryl) 0.07%.

Calories.—0.23 per gram; 6.5 per ounce.

Use.—In low calorie, low sodium, and other therapeutic diets.

Diet-Delight Brand Special Dietetic Pack Yellow Cling Peaches (Sliced)

This product consists of peaches packed in water with the addition of cyclamate sodium (Sucaryl).

Analysis (submitted by manufacturer).—Total solids 8.5%, moisture 91.5%, ash 0.3%, fat 0.02%, protein 0.4%, available carbohydrates (total sugar as invert) 5.2%, carbohydrates (by difference) 7.6%, crude fiber 0.2%, sodium 5.0 mg./100 gm., and cyclamate sodium (Sucaryl) 0.07%.

Calories.—0.23 per gram; 6.4 per ounce.

Use.—In low calorie, low sodium, and other therapeutic diets.

Diet-Delight Brand Special Dietetic Pack Bartlett Pears (Halves)

This product consists of pears of the Bartlett variety packed in water with the addition of cyclamate sodium (Sucaryl).

Analysis (submitted by manufacturer).—Total solids 8.2%, moisture 91.8%, ash 0.2%, fat 0.08%, protein 0.2%, available carbohydrates (total sugar as invert) 5.3%, carbohydrates (by difference) 7.0%, crude fiber 0.7%, sodium 4.0 mg./100 gm., and cyclamate sodium (Sucaryl) 0.07%.

Calories.—0.23 per gram; 6.4 per ounce.

Use.—In low calorie, low sodium, and other therapeutic diets.

ADRENALECTOMY FOR SEVERE HYPERTENSIVE VASCULAR DISEASE

The role of the adrenal in human hypertension has not been clearly defined. That it plays a part in maintenance of normal blood pressure and may play a part in production of hypertension is suggested by some experimental and clinical evidence. Goldblatt found that total adrenalectomy interfered with experimental renal hypertension unless adequate supportive and substitution therapy was given. He assumed that the adrenal glands might play an accessory role. The primary mechanism of nephrogenic hypertension seems to be renal anoxia, with liberation of renin, interaction of renin and a substrate or activator, and formation of a pressor substance (named angiotonin by Page and hypertensin by Houssay). The depressor effect of adrenalectomy in the Goldblatt experiments probably resulted from development of a deficiency state that in turn caused alteration of the peripheral vascular resistance so that maintained increase of blood pressure could not occur.

Clinical evidence of a relationship between the adrenal cortex and maintenance of normal blood pressure or hypertension is suggested by the hypotension of adrenal cortical hypofunction and the hypertension in adrenal cortical hyperfunction. The blood pressure of patients with essential hypertension in whom adrenal insufficiency develops may revert to normotensive levels. In patients with Addison's disease given large doses of desoxycorticosterone acetate hypertension may develop. Selye, Heinbecker, and others have advanced concepts of neurohumoral mechanisms by which repeated stress (alarm reaction) or abnormal function of the hypothalamus and the pituitary gland might cause adrenal hyperfunction; however, most patients with hypertensive vascular disease do not have signs or symptoms of adrenal hyperfunction or tumor.

The adrenal medulla secretes at least two substances capable of producing hypertension. Of these two, epinephrine increases cardiac output and peripheral vascular resistance, while arterenol (nor-epinephrine) acts

primarily by increasing peripheral resistance and has little effect on the heart. These two substances are responsible for the persistent, fluctuating, or paroxysmal hypertension of pheochromocytoma. Studies of these and other pressor amines have not yet established them as important in the usual forms of human hypertension. Removal of the medulla of the adrenal gland does not alter experimental renal hypertension; nor does removal alter Heyman's experimental neurogenic hypertension produced by section of the depressor nerves. Adrenal denervation and splanchnicectomy also fail; thus total sympathectomy is necessary.

The fact that administration of corticotropin aggravated hypertensive cardiovascular disease was additional evidence that a critical reduction of functioning adrenal cortex might lead to amelioration of the hypertensive disease process in intractable cases. Adson had performed partial adrenalectomies with his earliest splanchnicectomies, and others have tried unilateral adrenalectomy without improvement. That life can be maintained after a complete removal of adrenal tissue was demonstrated by Huggins in patients with metastatic cancer. The recent synthesis of cortisone, its relatively low cost, and its efficacy when administered orally, have made it possible to maintain patients with adrenal cortical hypofunction in good general health.

Green and his co-workers¹ performed a bilateral adrenalectomy on a 28-year-old woman with malignant hypertension and severe diabetes. As late as 15 months postoperatively there was a regression of the cerebral, retinal, myocardial, and vascular disturbances and marked improvement in diabetes. Encouraged by this observation two combined medical and surgical teams began a study of adrenalectomy, one at the University of Pennsylvania, including Drs. C. C. Wolferth, W. A. Jeffers, H. A. Zintel, F. D. W. Lukens, H. H. Hafaenschel, and others, the second at Harvard Medical School (Peter Bent Brigham Hospital), including Drs. D. W. Thorn, J. H. Harrison, J. P. Merrill, and others. Each team received grants and supplies of cortisone. Each entered into a detailed program of study, treatment, and follow-up observation.

Thorn² and his co-workers evaluated bilateral complete adrenalectomy in 15 patients. Eleven had advanced malignant hypertension; three had advanced glomerulonephritis causing marked renal insufficiency with vascular changes in the fundi; and one had chronic glomerular nephritis with minimal eyeground changes. Six of the patients died within 12 days of operation, one of cardiac arrest, one of coronary occlusion, one after brief symptoms of dizziness, and three with uremia. Four patients died between 3 and 12 months postoperatively, one with symptoms of weakness and dehydration, one of an acute vascular accident and coronary disease, one of congestive failure, and one with uremia. Five of the 15 patients were living one year to 18 months after operation. Two were considered greatly improved. One with minimal changes in the fundi before adrenalectomy lost edema and had reduction of blood pressure. The other with papilledema, hemorrhages, and exudates in the fundi no longer had

2. Thorn, G. W., and others: Clinical Studies on Bilateral Complete Adrenalectomy in Patients with Severe Hypertensive Vascular Disease, *Ann. Int. Med.* 37: 972-1005 (Nov.) 1952.

these abnormalities at 18 months but had diminishing renal function and increasing blood pressure. Three of the five survivors were considered less improved. Further reduction of renal function was evident in two, and there was no reduction of blood pressure in the third patient. Thorn and his co-workers observed that increased capacity to excrete sodium and chloride was the most striking physiological change observed. Marked clinical improvement was described in those patients who preoperatively showed evidence of excessive sodium and chloride retention. They thought it justifiable to explore further the usefulness of adrenalectomy in patients with rapidly advancing malignant hypertension, with reasonably adequate renal function, who failed to respond to medical therapy. Interesting as these studies are, death of 10 of 15 patients offsets hope that total adrenalectomy alone would be a helpful means for salvaging patients who cannot be aided by rigorous medical regimens or by sympathectomy.

Lukens,³ Wolferth,⁴ Jeffers,⁵ and their co-workers have presented reports as their group of patients has increased from 6 to 99. Lukens' group first reported that removal of 90% of all adrenal tissue in six patients produced striking improvement in severe advanced hypertension in one and some favorable changes in four. There was one death seven days after operation. Wolferth and his co-workers⁴ summarized observations when the series reached 23 cases. Removal of adrenal tissue ranged from 90 to 100%. Adrenalectomy had been combined with splanchnicectomy in 15 patients. Wolferth stated that subtotal adrenalectomy alone had reduced blood pressure in some cases with marked symptomatic improvement but that it had been necessary to remove more than 90% of adrenal tissue and create a grade of adrenal cortical insufficiency requiring at least minimal replacement therapy. Also combination of subtotal adrenalectomy and sympathectomy was thought to give more promising results than adrenalectomy alone.

The last report of this team⁵ is based on 99 patients, including those of the earlier reports. Duration of follow-up was 1 to 12 months in 54 patients, 13 to 24 months in 28, and 25 to 37 months in 17. Operative procedures are listed as total adrenalectomy alone for 2 patients, subtotal adrenalectomy alone for 11, total adrenalectomy with Adson or Smithwick splanchnicectomy in 24, and subtotal adrenalectomy with various forms of splanchnicectomy in 62 (in 49 of these 62 subtotal adrenalectomy with an Adson subdiaphragmatic splanchnicectomy was performed). Poor renal function, a stroke, or coronary occlusion less than six months previously, age over 55 years, and inability to cooperate in taking adrenal cortical replacement therapy were considered contraindications. Patients were classified before operation according to the system devised by Smithwick. Of 29 patients in group 2, two were dead and 12 had a blood pressure of less than 150/100 mm. Hg, lying and standing. Of 18 in group 3, 2 were dead and 5 had similar reduction of blood pressure. Of 52 patients in group 4, 20 were dead and 6 had this reduction of blood pressure. Only one of the 99 patients was considered a therapeutic failure in that blood

pressure, signs, and symptoms were unchanged after operation. Twenty-three had blood pressures above 150/100 mm. Hg when lying but less than 150/100 standing and 28 in whom the blood pressure was essentially unchanged had improvements of signs and symptoms. The authors state that they have chosen to combine the possible benefits of splanchnicectomy with subtotal or total adrenalectomy but that further observation will be necessary to establish whether or under what circumstances their operation will prove superior in the long run to (1) thoracolumbar sympathectomy, (2) thoracolumbar sympathectomy plus subtotal or total adrenalectomy, or (3) total adrenalectomy alone. They also observed that patients with paroxysmal dyspnea or congestive heart failure prior to operation showed the most striking improvement.

A few other medical and surgical teams are using adrenalectomy, and their evaluation will be important. At present it seems that the most striking change after adrenalectomy is increased capacity to excrete sodium and chloride. Greatest clinical improvement occurred in patients with clinical edema, paroxysmal dyspnea, or congestive heart failure. Results of adrenalectomy in these patients will need to be evaluated against improving medical regimens, diet, and drugs. Adrenalectomy has not prevented progressive renal failure.

There is evidence that the contraindications adopted for sympathectomy also may apply to adrenalectomy. These are azotemia, marked encephalopathy, advanced cardiac damage, and age much exceeding 50. Results of adrenalectomy or of adrenalectomy and splanchnicectomy in patients who do not have these contraindications will need to be evaluated against results of newer medical treatments, sympathectomy alone, or sympathectomy supplemented by use of newer drugs or diets. Survival after adrenalectomy among the patients for whom it was employed, one-third and three-fourths respectively for the two groups, seems low considering the relatively short period of follow-up observation. Obviously sympathectomy was contraindicated in some but not all of the patients who died. The survival rate for thoracolumbar splanchnicectomy (Smithwick⁶), is 70% at 4 to 12 years and that for total sympathectomy (Grimson⁷) is 84% at 5 to 10 years. Only long-term studies of patients who could have had sympathectomy alone and instead had adrenalectomy with splanchnicectomy will determine which procedure is preferable. The constant need for observation and variation of replacement therapy with

risk of death from adrenal insufficiency may adversely affect survival after adrenalectomy and splachnicectomy, or benefits of the procedure might compensate for this hazard and yield improved survival. Similarly, long-term results of improved medical regimens developed during the last few years must be compared with those of surgical procedures before the limitations of each are known.

Adrenalectomy is possibly indicated for patients retaining salt and water. The high incidence of disappointing clinical results after total or subtotal adrenalectomy alone in patients who do not retain salt and water suggests that any role of the adrenal glands in this more usual form of severe hypertensive vascular disease is subordinate to other causes. The indications for adrenalectomy are not yet established. The advantage of adding adrenalectomy to splachnicectomy, sufficient advantage to offset the risk associated with constant need for carefully regulated replacement therapy, also is not yet established.

BLOOD DYSCRASIAS

Data on the etiology and incidence of the hypoplastic anemias are inaccurate and incomplete, since few states or municipalities require reports of these diseases. Information available is generally based either on personal experience in practice or on mortality statistics, and yet it is known that certain physical and chemical agents play a direct causative role in this group of diseases. In addition, a large number of hypoplastic anemias are classified as idiopathic, which suggests that unsuspected agents may be responsible.

The known causative agents may be divided into two groups. The first consists of agents that if administered in a large enough dose cause varying degrees of bone marrow depression and damage in all human beings or exposed experimental animals. Examples of this group are benzol, the antifolic compounds, x-ray irradiation, and the nitrogen mustards. The second group consists of agents that have bone marrow depressant effects in a small, often insignificant percentage of exposed persons but do not have similar effects in experimental animals. Most of the drug-caused anemias belong to this second category. Perhaps the syndromes observed are peculiar to the human species and may be in the nature of allergic or immunologic reactions. It does seem significant that these blood dyscrasias appear predominantly in patients with an allergic history and generally, but not necessarily, after several exposures to the precipitating agent. Possibly the lack of response in experimental animals may be due to the impracticability of testing sufficiently large numbers over a long enough period of time, or it may be due to an inherent insusceptibility of test animals. Such speculation at present probably is immaterial; the fact remains, no practical animal homologue exists that will enable pharmacologists to detect the bone marrow depressant potentialities of new compounds. Although

attempts have been made to predict antihematopoietic properties of new compounds on the basis of chemical structure, these efforts have not been too successful.

The danger exists that among the many newly introduced and often widely used therapeutic and household agents there may be some that have profound depressant effects on the hematopoietic system. Tragic experiences recited to the Council on Pharmacy and Chemistry and its Committee on Research led to the realization that continuation of the present sometimes improperly organized and even haphazard method of reporting would not prevent occurrence of similar episodes in the future. Reporting of drug-caused dyscrasias must be improved, and the information on possible causative agents speedily brought to the attention of the profession to avert needless exposures.

The Committee on Research of the Council on Pharmacy and Chemistry has organized a Subcommittee on Blood Dyscrasias for the twofold purpose of developing methods for the earliest possible reporting of drug-induced blood dyscrasias and of seeking out new methods of experimental approach that might enable more accurate prediction of potential danger from new therapeutic agents. The subcommittee has met and has adopted a specific course of action. It believes the best method for securing accurate information on toxic reactions of the hematopoietic system is to enlist the cooperation of selected hematological centers in various parts of the country. Sixty such centers have been invited to report cases of hypoplastic anemia to the offices of the Committee on Research on a standard report form specifically designed for the purpose. *These reports will be filed monthly and will be scanned and analyzed by the staff of the Committee on Research.* The resultant data will be published from time to time in *THE JOURNAL*; however, if returns indicate that a recently introduced agent is suspected as the responsible cause in several cases, attention will be called immediately to it in *THE JOURNAL*.

To fulfill the second objective, that is, to find new research approaches to the problem of blood dyscrasias caused by drugs, the subcommittee will arrange a symposium attended by scientists trained in many disciplines, for example, hematologists, immunologists, pharmacologists, allergists, and biochemists. It is hoped that after a complete discussion of the experimental problems by hematologists the wide experience of the conferees may suggest some clue that will lead to more accurate appraisal of potential hazards in new agents.

The projected program provides for organized reporting, but this does not mean that the subcommittee is not interested in reports of individual cases seen by physicians in practice; in fact, all physicians are invited to report their cases of hypoplastic anemias directly to the Secretary of the Committee on Research at A. M. A. headquarters. It is entirely possible that this latter course of action may be the most important on occasion when some hitherto unexpected toxic property is found to be inherent in one of the newer remedies.

ORGANIZATION SECTION

The following paper by Dr. Gunnar Gundersen of La Crosse, Wis., a member of the Board of Trustees of the American Medical Association, was read before the midyear conference of the American Hospital Association, Feb. 6, 1954.

BENEFITS OF HOSPITAL ACCREDITATION TO THE MEDICAL PROFESSION

The subject assigned to me for discussion is really very simple. In order to over-simplify it, it might well be said that there are only benefits to be derived, and no disadvantages. The profession of medicine may at times be vocal in its criticism of the accreditation program because it imposes on the medical man certain musts in the discharge of his daily routine. But the thoughtful physician, if he is faithful to his pledge, will, in his own conscience, have no criticism if he stops for a moment to reflect that the final or acid test of a project or program is "the ultimate good for the patient who is entrusted to his care." After all is said and done, the care and welfare of the patient is the only valid measuring stick by which a true evaluation of a project can be made.

Dr. Fred Rankin, president of the American College of Surgeons, in his invocation speech in Chicago last fall, commented on the accreditation program as follows: "The standardized, accredited hospital is a pillar in the edifice of modern surgery, and a most important one. It has two functions. The first is its teaching function. The second is the protection of the patient. This means the enforcement of standards determined by the medical profession and based only upon professional ability and moral integrity. In plain words, this means that staff privileges should be limited exclusively to qualified surgeons. It means that only qualified surgeons, or surgeons who work under supervision in the process of qualification, should be permitted operating room privileges.

"I have no illusions about these requirements. This is a program which is neither simple to set up nor easy to administer in hospitals not associated with teaching institutions and not provided with independent financial support. Nevertheless, every hospital has a moral responsibility in this matter. It must insist that professional attainment and moral character shall determine the composition of the hospital staff.

"Progress in the hospital standardization program has been spectacular in some respects and slow in others. A great step forward was taken when the Joint Commission on Accreditation of Hospitals was recently set up, under the auspices of the American College of Surgeons, the American Medical Association, the American Hospital Association and the Canadian Medical Association. This program cannot fail. It will inevitably have a most salutary effect upon the whole hospital picture. It should improve hospital economics. It should elevate professional performance. Finally, it should modify and improve our public relations, which at the moment are sadly in need of reformation and revitalization."

Let us stop for a moment and take a look at the situation as it existed before the American College of Surgeons undertook its accreditation program, less than forty years ago. You are all familiar with the sad tale of the first report on accreditation. The story is now so familiar to all of you that it hardly needs repetition, but for comparison I invite you to share it with me. Briefly, the state of affairs in hospitals in this country, with very few notable exceptions, was so deplorable that the regents of the college were fearful of the implications and repercussions resulting from public knowledge of the true facts, and they decided to and did burn the first report of the Commission on Hospital Standardization in the furnace of the old Waldorf-Astoria Hotel in New York City. Now, a little over a generation later, we take justifiable pride in the conditions in hospitals of this country and Canada and the type of care a patient is capable of receiving. The one outstanding reason for this change, and it can be said without fear of contradiction, is due to the accreditation program. A conscientious physician is interested in one thing, primarily, and that is only the opportunity to practice good

medicine. The hospital, which is his workshop, provides him with the tools and facilities so that he can do a job well. Therefore, the doctor, from his own selfish point of view, is primarily concerned with hospital accreditation, as it assures him of an environment in which he can best carry out the type of work to which he has devoted a lifetime of study and application.

Up to the present, you may accuse me of dealing in platitudes and generalities, but let us be more specific and go briefly into a few of the desirable activities of the accreditation program. The ones I shall mention are all-important but do not by any means "cover the water front," and are not being discussed necessarily in the order of their importance.

1. *Self-Discipline.* The necessity for keeping accurate and detailed histories imposes self-discipline on the physician. The possibility of overlooking details, which may later prove to be of major importance, is obviously reduced to a minimum if detailed records are insisted upon. The final result is better medicine.

2. *Staff Meetings and Conferences.* The regular meetings of the staff, either at the regular monthly meeting or in the many staff committees, results in self-policing of the staff member to the end that better care of the patient results and, as stated previously, this again is the primary purpose of accreditation. It means better medicine.

3. *C. P. C.'s.* No one would seriously question the great educational value of the clinicopathological conference. In fact, there is probably nothing in medicine which has greater elements of good from an educational point of view than a well-conducted, well-prepared, and well-organized clinicopathological conference. The result is better medicine.

4. *Tissue Committee.* A more recent addition to the accreditation program will most assuredly result in reduction or abolishment of some of the evils in the practice of medicine of which we have heard so much recently in the press and lay magazines. An alert, conscientious tissue committee has in it the elements which would put a prompt end to unnecessary surgery. The "rape of the female pelvis," unnecessary appendectomies, and removal of normal tissue would be reduced to a minimum. Again, better medicine.

5. *Evils of Medical Practice.* After a generation of medical practice spent in the field of surgery in a fairly typical American city of moderate size, I feel that I have some competence in speaking on the subject, based on my association with men of medicine in my immediate area and surrounding states. I have become increasingly impressed with the fact that the majority of my colleagues are men of unquestioned integrity who are doing the best possible job in their chosen profession within the limits of their ability. I could point to but a few who would deliberately practice bad medicine. The tragedy is that the occasional miscreant may stigmatize the entire profession. No one holds a brief for the occasional few who give the entire profession of medicine a black eye. The conscientious man of medicine is opposed to the evils whether it be ghost-surgery, fee-splitting, fee-gouging, or unnecessary surgery. Organized medicine has the weapons to put an end to all of this if it were but willing and had the determination to do so. The mechanics of dealing with the problem may vary, as do those that exist in a special society such as the American College of Surgeons, where the initiative can be taken from the top echelon, from those that exist in the American Medical Association, which is an entirely democratic organization based on the local county society where the initiative in disciplining a member must be carried out at the local level. However, the most potent force we have, in my judgment, for disciplining the malefactors amongst us exists in the accreditation program. Through the various agencies mentioned previously in the accreditation program, there exists the elements which will eventually upgrade medical practice, from both a scientific point of view and an ethical point of view. The result again, better medicine.

Freedom has made this country strong. Its accomplishments during its less than two centuries is the marvel of the modern world. Freedom has created the modern hospitals of today. They

have, in large measure, grown and developed on a free, voluntary basis. Freedom has seen our voluntary hospital and medical care programs develop at a rate of speed and to a size believed to be beyond achievement, and the end is not yet in sight. Freedom has seen the development of medical science and medical practice in this country, which is second to none. Freedom has made all this possible without compulsion, without government enactment, without police action, and without licensure. Hospital accreditation is freedom in action. It has resulted in the raising of the quality of medical care in the hospitals of the United States and Canada and the relationship of the total hospital-family (the physician, the trustee, and the administration) to it. If you and I can hold fast to freedom, the future has nothing to fear.

COLORADO STATE MEDICAL SOCIETY

Before Colorado attained statehood, the Colorado Territorial Medical Society was founded by 25 physicians Sept. 19, 1871, in Denver, which had welcomed its first railroad the previous year. At that time the population of Colorado (now more than 1,325,000) was about 40,000 and that of Denver, which now is

The Republic Building, Denver, in which the Colorado State Medical Society occupies Suite 835.

over 415,000, was 5,000. Colorado's early history contains the names of Dr. John H. Robinson, a surgeon, probably the first medical practitioner in Colorado, who had volunteered to accompany Lieut. Zebulon Pike on his expedition in 1806-1807 and of whom Pike wrote, "As a gentleman and companion in dangers, difficulties, and hardships, I in particular, and the expedition generally, owe much to his exertions"; and Dr. Edwin James, "who came with the expedition of Major Stephen H. Long in 1820, and distinguished himself not only in his professional capacity but by being the first to ascend Pike's Peak." Before the founding of the Colorado Territorial Medical Society, the Jefferson Medical Society had been organized in a log cabin on June 6, 1860; but, according to the "Historical Notes of the Colorado State Medical Society," gathered by Dr. Walter A. Jayne, "Its rise and fall were alike speedy. The civil strife into

which our country was plunged in 1861 drew to itself most of its founders. . . . These were led, according to their convictions, into the Union Army, or south to the Confederate service, and the embryo Society, left to itself, perished from inanition. Thus was Colorado bereft of its first-born, and no other Society was established until 1868, which, owing to internal dissensions, was as short lived as the first, and yet another was formed, but cohesiveness and durability were not among their attributes, nor have we any records of these first fruits of medical union. But in 1871 a lasting association was finally established. . . ." That society, the Denver Medical Association, now known as the Medical Society of the City and County of Denver, on June 16, 1871, resolved to call the convention that resulted in the formation of the Colorado Medical Society, more commonly referred to as the Territorial Medical Society.

Soon after Colorado was admitted to the Union in 1876 as the "Centennial State," the society reincorporated under its present title. When first organized it affiliated with the American Medical Association, and in 1902, conforming with the reorganization of the Association, the society reorganized with component county and district societies and a house of delegates. In 1931 it again rewrote the state charter, modernizing its internal structure by assigning its executive functions to a board of trustees and its judicial functions to a board of councilors. Its board of supervisors, a part of its state-wide system of investigation and internal self-discipline, is the prototype after which many other societies have fashioned their grievance committees. Its "Code of Ethics" between the medical and hospital professions and the press, radio, and television industries, has also served as a model, as has its policy, adopted by its component societies, to publicize average community fee schedules. Excellent public relations are maintained through its own fully dramatized local-interest weekly radio program, "Dr. Tim, Detective," which won the 1950 award from Ohio State University's Institute for Education by Radio, and also by its weekly health feature, "Old Doc Experience," a health column, developed by the society in cooperation with the Colorado Press Association, which has been used for many years by many Colorado newspapers. For several years a special committee has also presented an annual series of articles for ranch and farm magazines.

The society's long campaign to reorganize the Colorado State Health Department culminated in 1947 with the passage of eight companion acts by the state legislature, generally known as the "Sabin Bills," public leadership of the campaign having been centered around the late Dr. Florence R. Sabin, who had returned to Colorado after retiring from her work with the Rockefeller Foundation. Earlier, in 1937, another long campaign of the society had resulted in passage of a basic science act in Colorado. The society is currently engaged in a campaign against stream pollution and a similar drive for reduction of automotive injuries and fatalities. Its general activities are carried out through its three boards of trustees, councilors, and supervisors; 31 standing committees, including 11 on public health; 8 special committees; and several liaison representatives to other professional and civic organizations.

The society publishes the *Rocky Mountain Medical Journal*. During the early years of its organization the society published the annual "Transactions," which it replaced in November, 1903, with a monthly medical journal *Colorado Medicine*, changed in January, 1938, to *Rocky Mountain Medical Journal*. The periodical is owned by the Colorado society through its board of trustees but is edited under the direction of a five-state editorial board under agreements between the medical associations of Colorado, Wyoming, Utah, New Mexico, and Montana, for a nonprofit plan of publication with proportionate usage of journal space. These states are further linked by the Rocky Mountain Medical Conference, a biennial scientific meeting managed by a five-state committee, with the meeting place rotating among the participating societies. In addition to this biennial co-sponsored conference, the Colorado State Medical Society conducts three major annual medical meetings: a four-day annual session, held usually in September in Denver, Colorado Springs, or Estes Park; a three-day interim meeting, known as the Midwinter Postgraduate Clinics, held each February in Denver; and the two-day Rocky Mountain Cancer Conference, sponsored jointly with the Colorado division of the American Cancer Society and held each July in Denver. The society also co-sponsors with the

University of Colorado School of Medicine, Denver, a continuing group of postgraduate courses offered to component societies in smaller population centers throughout the state. The state organization is composed of 26 county and district societies, the largest being Colorado's only metropolitan society, the Denver Medical Society, which itself amounts to 45% of the total state membership. This society is currently constructing a \$35,000 medical library building, to be ready for occupancy late this summer, which will house the Denver society's office and its information and referral center. The headquarters of the state medical society in the Republic Building, as seen in the illustration, consists of a reception room, a conference or committee room, six office rooms, a mail room, and a storage room. Since June 1, 1929, the executive office has been under the direction of Harvey T. Sethman, executive secretary. The staff includes eight full-time and two part-time members. The society's current membership of 1,791 represents 90% of the licensed doctors of medicine living in Colorado. Its officers include: Dr. Claude D. Bonham, Denver, president; Dr. Samuel P. Newman, Denver, president-elect; Dr. Lawrence D. Buchanan, Wray, vice-president; Dr. Irvin E. Hendryson, Denver, constitutional secretary and chairman of the board of trustees; and Dr. Frank I. Nicks Sr., Colorado Springs, treasurer.

UNIVERSITY HONORS A. M. A. PRESIDENT

The University of Toledo in Ohio on Feb. 12 conferred the honorary degree of Doctor of Civil Law on Dr. Edward J. McCormick, President of the American Medical Association. The citation stated that the President of the A. M. A. has "earned the respect and gratitude of colleagues in [his] profession and that of fellow citizens in northwestern Ohio." It further extolled Dr. McCormick's "ability and leadership" in the field of medicine. Toledo is Dr. McCormick's home town.

FEDERAL MEDICAL LEGISLATION

Malnutrition

Senator Douglas (D., Ill.) proposes in S. 2901 to direct the Secretary of Health, Education, and Welfare, the Administrator of Veterans' Affairs, and the War Claims Commission to make a study of mental and physical consequences of malnutrition in prisoners of war and civilian internees in World War II and the Korean War. Results of the study would be used to extend practice "for the purpose of determining: (1) the procedures and standards to be applied in the diagnosis of the mental and physical condition of former prisoners of war; (2) the life expectancy of former prisoners of war; (3) whether there is evidence to sustain a conclusive presumption of service connection in favor of former prisoners of war for purposes of hospitalization in Veterans' Administration facilities; and (4) standards to be applied for the evaluation of claims of American civilian and military personnel based upon the physical and mental consequences of the conditions of their imprisonment in the event such claims are later made compensable." This bill was referred to the Committee on Labor and Public Welfare. Congressman Fulton (R., Pa.) has introduced an identical bill, H. R. 7711, which was referred to the Interstate and Foreign Commerce Committee.

Social Security Increases

Senator Long (D., La.) has introduced a bill, S. 2929, amending the social security act "to increase Federal financial participation in State programs for old-age assistance, aid for dependent children, aid to the blind, and aid to the permanently disabled, in order that the States may make appropriate adjustments in their payments to beneficiaries under such programs to provide for the increased cost of living." He proposes a \$10 monthly increase from the present maximum of \$55 for the aged, blind, and permanently disabled. The federal contribution is increased from the present four-fifths of the first \$25 and one-half of balance to four-fifths of the first \$25 and five-eighths of the balance up to the new maximum of \$65. The federal aid to dependent children would be increased from the present four-fifths of the first \$15 and one-half of the balance to four-fifths

of first \$18 and five-eighths of balance up to \$36. The last federal increases were made in 1952, and will end Sept. 30. The proposed bill has no automatic termination clause. It was referred to the Finance Committee.

Extending Water Pollution Control Act

Congressman Cannon (D., Pa.) in H. R. 7644 proposes to extend for three additional years (until June 30, 1959), the water pollution control act. This would provide federal assistance to states through study, advice, and grants. The Cannon proposal would permit loans to states and municipalities for construction of sewage treatment works to a total of 40 million dollars annually. Present authorization is \$22,500,000 closed premises, and doubles a maximum amount of loan per project from \$250,000 to \$500,000 or from 33⅓ to 66⅔% of the cost, whichever is smaller. The annual interest rate is raised from 2 to 2½%. The bill was referred to the Public Works Committee.

Limiting VA Outpatient Dental Care

Congressman Frelinghuysen (R., N. J.) in H. R. 7653 extends a restriction now in the law as a part of the second independent offices appropriation act of 1954, which expires June 30. This provision restricts the outpatient dental treatment to veterans with service-connected complaints and is in line with President Eisenhower's budget recommendations. The bill was referred to the Veterans' Affairs Committee.

Medical and Dental Expense Deductions

Congressman Whitten (D., Miss.) in H. R. 7681 would remove limitations for deductions for medical expenses from gross income in calculating income tax. This bill is essentially similar to H. R. 3911. The present law allows deductions only when they exceed the 5% income. The bill was referred to the Ways and Means Committee.

Mortgage Insurance for Medical Facilities

Congressman Wolverton (R., N. J.) proposes in H. R. 7700 to provide federal mortgage insurance for private loans for the construction of medical facilities supplying voluntary, prepayment, group practice medical care. Medical facilities include hospitals, diagnostic or treatment centers, personal health service centers, rehabilitation facilities, and offices for physicians and dentists. A medical facilities mortgage insurance fund would be created under the Surgeon General of the U. S. Public Health Service with \$2,500,000 allocated immediately and additional annual appropriations as necessary. The Surgeon General could borrow up to 5 million dollars from the U. S. Treasury to carry out the program. The aggregate amount of all outstanding mortgages could not exceed 1 billion dollars except, with the approval of the President, it could be increased another 250 million dollars. To obtain insurance, a mortgage could not exceed 5 million dollars, have a maturity over 40 years, bear interest in excess of 6% (6½% in certain mortgage markets), and reserve less than 60% of the insured medical facility for serving members of group practice, prepayment health plans. This bill, which supersedes H. R. 6951 previously reported, was referred to the Interstate and Foreign Commerce Committee.

Social Security Extension

Congressman Williams (D., N. J.) proposes in H. R. 7713 to extend the old age and survivors insurance system to provide permanent and total rehabilitation benefits. This social security coverage is extended to self-employed persons but does not include physicians or dentists. The bill, which is identical with S. 2260 and 22 other House bills previously reported, was referred to the Ways and Means Committee.

Health Insurance Premiums Withholding for Federal Employees

Congressman Roberts (D., Ala.) has introduced H. R. 7742, which would authorize on request the withholding from salaries of federal employees premiums paid for voluntary, prepayment plans and insurance for hospital and medical care. This bill, which is identical with S. 2191 and S. 2260, was referred to the Committee on Post Office and Civil Service.

The summary of federal legislation was prepared by the Washington Office of the American Medical Association and the summary of state legislation by the Bureau of Legal Medicine and Legislation.

Oral Narcotic Prescriptions

Congressman Martin (R., Iowa) in H. R. 7817 would permit the sale of narcotic drugs that possess little or no addiction in comparison with morphine, codeine, or cocaine on an oral prescription of a registered physician, dentist, veterinary surgeon, or other authorized practitioner. In issuing an oral prescription, the same information that is now required on written prescriptions would be necessary and would be put in writing promptly and filed with the druggist or dealer. The Secretary of the Treasury would determine what narcotic drugs could be prescribed orally. He would consider the views of the Public Health Service, the Food and Drug Administration, and the secretaries of national associations representing physicians, pharmacists, and narcotic drug manufacturers. This bill is being supported by the National Association of Retail Druggists. It was referred to the Ways and Means Committee.

STATE MEDICAL LEGISLATION

Arizona

Bills Introduced.—H. 241, relating to the practice of medicine and surgery, proposes, among other things, that the examination of applicants shall include an examination in the subjects of obstetrics, pharmacology, materia medica, general surgery, clinical medicine, public health and hygiene, bacteriology, and pediatrics, in addition to subjects already mentioned in the existing law. H. 242, declares it to be the public policy of the legislature that steps be taken to acquire and construct additional facilities for the care, treatment, and isolation of persons suffering from tuberculosis and proposes a method of accomplishing this policy.

Kentucky

Bills Introduced.—H. 356, proposes the creation of a Kentucky state board of masseurs and masseuses and defines massage as the treatment of superficial soft parts of the body for remedial or hygienic purposes, consisting of rubbing, stroking, kneading, or tapping with the hand or an instrument. H. 383, proposes certain amendments to the chiropractic practice act including a definition of chiropractic that would authorize licentiates to treat with analgesics, antipyretics, and codeine, orally, and antibiotics or sulfanilamide agents through local application. H. 384, proposes regulations for the control of rabies. H. 387, proposes to authorize county hospitals to purchase liability and indemnity insurance for the protection of their patients against the negligence of the employees of such hospitals.

Maryland

Bill Introduced.—S. 54, proposes the enactment of a temporary disability insurance law.

Bill Enacted.—S.R. 5, was adopted Feb. 11, 1954. It resolves that the legislative council be requested to investigate the feasibility and manner of making available to subscribers to the Blue Cross Plan the benefits of the Blue Shield program of benefits.

Michigan

Bills Introduced.—H.R. 16, proposes the appointment of a special committee to investigate the shortage of doctors of medicine in the state of Michigan. S. 1129, proposes to authorize the use in court, in cases in which paternity is a relevant fact, the results of blood grouping tests made of the other child and alleged father and authorizes the court to order such tests to be made. The proposal further provides that if the court finds that the conclusions of all the experts, as disclosed by the evidence based upon the tests, are that the alleged father is not the father of the child, the question of paternity shall be resolved accordingly.

Mississippi

Bill Introduced.—H. 536, proposes that all persons over the age of 15 years residing in the state and designated by the state board of health shall be examined and x-rayed and otherwise tested for tuberculosis and shall be given an approved serologic test for syphilis every two years.

New Jersey

Bills Introduced.—A.J.R. 2, proposes the creation of a commission to investigate nonprofit hospital and medical-surgical plans operating in the state as to premiums being assessed and the reasonableness of the rates being charged to policyholders. A. 171, proposes the enactment of a temporary disability benefits law. S. 67, proposes the establishment of a state medical and dental college to be affiliated with the State University of New Jersey. S. 79, proposes that every physician within 12 hours after his diagnosis that a person is ill or infected with a communicable disease or other disease, required by any law of the state or the state sanitary code to be recorded, shall report such diagnosis and related information as may be required by the state department of health. In cases of venereal disease, the report would be made to the state department of health and in other cases to the health officer designated by the local board of health.

New York

Bills Introduced.—A. 1118, proposes to require applicants for an operator's or chauffeur's license to pass such eye tests as will satisfy the commissioner that he is visually competent to operate a motor vehicle or, in lieu thereof, to produce a certificate from an eye physician, ophthalmologist, oculist, or optometrist attesting that he has been examined and found visually competent. A. 2174, to amend the public health law, proposes the establishment in the state department of health of an adult hygiene and geriatrics program designed to improve and protect the health and vitality of middle-aged and elderly citizens of the state. A. 2207 and S. 2213 propose to require applicants for a chauffeur's license to pass certain eye tests or else furnish a certificate from a physician or optometrist. A. 2226, proposes an appropriation to the state department of health for the purpose of conducting a pilot experiment in the physical rehabilitation of older persons and a community demonstration project in physical rehabilitation in a small and moderate-sized community. A. 2324 and S. 1937, proposes the establishment as a part of the department of health of a heart institute to conduct, assist, and foster research and investigation relating to the cause, prevention and methods of diagnoses and treatment of heart diseases. A. 2417 and S. 2122, propose that the board of hospitals of the city of New York shall have the power and it shall be its duty, upon the request of a patient at the time of his discharge from any hospital, to require such hospital to furnish the patient with a complete history of admission and operation notes. A. 2595, to amend the workmen's compensation law, proposes to require copies of every report of examination, finding, and opinion of a physician or medical consultant to be transmitted to the claimant or his authorized representative. A. 2596, to amend the workmen's compensation law, proposes that all physicians designated to conduct special examinations shall be prohibited from examining, treating, or prescribing for any claimant for compensation in a case other than for the purpose of making such special examinations and their reports thereon. S. 2031, to amend the insurance law, proposes that membership corporations organized for the purpose of furnishing medical expense indemnity shall provide such medical care through any duly licensed physician of the subscriber's choice whether or not designated or approved by the corporation. S. 2044, to amend the penal law relating to violations of the public health law with respect to narcotic drugs, proposes that no overt act is necessary in establishing a conspiracy to violate the public health law with respect to narcotic drugs. The agreement to violate the law would be sufficient in and of itself. S. 2181, to amend the education law, proposes the creation of 100 state scholarships to legal residents of the state who are registered professional nurses for the purpose of advanced education in teaching or administration of nursing. S. 2182, proposes the establishment of 1,000 state scholarships for attendance at schools of nursing for the training of professional nurses. S. 2252, proposes the creation of a temporary state commission to study, examine, and propose definite educational standards and provide for the licensing of all persons with the exception of all doctors who prescribe or sell hearing aids. S. 2263, to amend the vehicle and traffic law, proposes that a physician shall not be liable for damages in any civil suit for withdrawing blood for the purpose of determining the alcoholic content thereof, except for gross negligence in the performance of such withdrawal, when the withdrawal has been at the request of a police officer. S. 2709, proposes hospitals, infirmaries, clinics, and so forth, shall be liable for damages for personal injuries sustained by any person or for death resulting from the negligence or malpractice of a physician, surgeon, nurse, or other person employed by such institution and that nothing in the proposal would be construed to grant immunity from liability for such damages to any physician, surgeon, nurse, or other person for or on account of any such act of negligence or malpractice.

Rhode Island

Bill Introduced.—H. 543, proposes the creation of a special commission to study and report upon the feasibility of setting up a medical school at the University of Rhode Island. H. 634, proposes certain general amendments to the workmen's compensation act, among which is the provision that any injured employee shall at all times be entitled to treatment, care or rehabilitation by a physician, dentist, or hospital of his own choice.

Virginia

Bills Introduced.—H. 681, proposes to direct the Medical College of Virginia to establish and maintain a mobile psychiatric clinic to provide the services and perform the functions set forth in the act for children who have been committed to the department of welfare and are being held in any institution maintained by such department in Richmond or adjoining counties and at the training schools maintained by the department. S. 330, to amend the medical practice act, proposes that any applicant who is a citizen of the United States and who has studied medicine in a foreign medical school for at least three years and who has studied medicine in the United States for at least one year and who has been admitted after examination, to practice medicine in at least two states, and who has served an internship and residency in a general hospital for at least two years, and who, in addition thereto, has practiced medicine for at least six years in the United States, and who in addition thereto has served as a medical officer for at least two years in the armed forces of the United States, shall be permitted to take an examination for a license to practice medicine and shall be admitted to practice upon successfully passing this examination, provided that the applicant obtains a medical qualifying certificate from the state board of education, furnishes evidence of good moral character, and has resided in this state for at least two years immediately preceding his application.

MEDICAL NEWS

ALABAMA

Tom Spies Honored.—At a luncheon in Birmingham, arranged by the council of the Southern Medical Association, Dr. Tom D. Spies, director, Nutrition Clinic, Jefferson-Hillman Hospital, Birmingham, was cited "on completion of 25 years of unselfish service to humanity in the field of research, during which time he has given unsparingly of himself and his talents to study and devise better methods of recognition and treatment of disease." Mr. Hugh Comer, chairman of the Alabama Spies Committee, accepted the citation for Dr. Spies. Dr. Mario J. LeRoy, secretary-general of the Cuban Society of Public Health and of the Finlay Institute, Havana, Cuba, where Dr. Spies also has a clinic, presented to him an honorary membership in the Cuban Society of Public Health. Congratulatory telegrams were read from Dr. Louis H. Bauer, Hempstead, N. Y., Past President of the American Medical Association, and Dr. Guillermo Garcia Lopez, president of the University of Havana, at which Dr. Spies is an honorary professor.

CALIFORNIA

Conference in Ophthalmology.—Stanford University School of Medicine will present the annual postgraduate conference in ophthalmology, March 22-26. Registration is open to 30 physicians who limit their practice to the treatment of diseases of the eye or of the eye, ear, nose, and throat. Information may be obtained from the Dean, Stanford University School of Medicine, 2398 Sacramento St., San Francisco 15.

Case of Typhus.—According to the U. S. Public Health Service, a 28-year-old woman became ill the day she returned from three weeks in Hawaii. The symptoms, generalized aching, prostration, chills, fever, and sweating, were followed in two weeks by a faint red rash on forehead and abdomen that lasted about a day. During the trip the patient had never been alone or off the streets frequented by everyone else, and no pets were seen to and from, or on the islands. The Weil-Felix reaction was positive in a dilution 1:320 on the 11th day of illness and positive 1:1280 on the 18th day, and the complement fixation test was positive in a dilution 1:8 on the 11th and 18th days after onset.

CONNECTICUT

School of Alcohol Studies.—The Summer School of Alcohol Studies of the Laboratory of Applied Physiology, Yale University, will hold its regular annual session July 5-29 and a special session for nurses July 29-31. Among the topics to be discussed are "Society and the Problems of Alcohol," "The Psychological Effects of Alcohol," "Theories Concerning the Nature of Alcoholism," and "Theories Concerning the Treatment of Alcoholism." Starting in the second week of the school the afternoons will be devoted to seminars, which will include a rehabilitation seminar and a medical therapy seminar. Applications must be submitted by April 1 to Summer School of Alcohol Studies, 52 Hillhouse Ave., Yale Station, New Haven. The fee of \$250 covers university registration, tuition, room, and board (18 meals weekly).

DISTRICT OF COLUMBIA

Institute on Cardiac Rehabilitation.—The Washington Heart Association is sponsoring an Institute on Cardiac Rehabilitation for nurses, social workers, and therapists, March 18, 1-5 p. m., at the Medical Society of the District of Columbia, 1718 M St., N. W., Washington. Local physicians who will participate in the program include Josephine J. Buchanan, W. Proctor Harvey,

and Andrew G. Prandoni. Information may be obtained by calling Mrs. Lewis at the Washington Heart Association, STerling 3-1397.

Kellogg Lectures.—The George Washington University School of Medicine in Washington, is presenting the annual Kellogg lectures at the school, 1335 H St., N. W., beginning at 8:30 p. m. On March 3, "Terminal Care for the Gynecologic Cancer Patient" was discussed by Dr. Norman Fritz Miller, University of Michigan Medical School, Ann Arbor. The following lectures will complete the series:

- March 15, Pathogenesis and Management of Coronary Atherosclerosis, Thomas Morton Durant, Philadelphia.
- March 17, Emotional Problems in Heart Disease, Edward Weiss, Philadelphia.
- March 29, Management of Visceral Trauma, Edward Mather Kent, Pittsburgh.
- April 1, Problems in Abdominal Surgery in Infancy and Childhood, Marcus Mitchell Ravitch, New York.

Society News.—The District of Columbia Society for Crippled Children is sponsoring lectures at its headquarters, 1767 Massachusetts Ave., N. W., Washington. The following topics are scheduled for presentation from 3:30 to 4:30 p. m.:

- March 16, Behavior Problems in Children, Thelma Hunt, Washington, D. C.
- March 23, Psychosomatic Aspects of Brain Damage, John R. Cavanagh, Washington, D. C.
- March 30, Education of the Brain-Damaged Child, Mrs. Miriam Tanhauser, supervisor of education, Montgomery County.
- April 6, D. C. Public School System and the Brain-Damaged Child, Carl Hansen, Ph.D., assistant superintendent of schools, Washington, D. C.
- April 27, Future of the Brain-Damaged Child, James F. Garrett, Ph.D., director of program services, Department of Health, Education, and Welfare, U. S. Public Health Service.

ILLINOIS

Lecture on Operational Psychotherapy.—Dr. Jacob E. Fine-singer, professor of psychiatry, University of Maryland School of Medicine, Baltimore, will discuss "Operational Psychotherapy" at Veterans Administration Hospital, Downey, 10 a. m. March 17. Discussion of a case presentation is scheduled for 1 p. m.

Tuberculosis Conference.—The Tuberculosis Institute of Chicago and Cook County will hold its annual tuberculosis conference at the Hotel Sherman, Chicago, March 18-19. The Thursday afternoon session, co-sponsored by the Chicago Tuberculosis Society, will present a picture of the workings of the Municipal Tuberculosis Sanitarium. On Friday morning the theme will be "Tuberculosis—A Community Problem," during which a panel "The People—How Much Do They Know About Tuberculosis?" will be presented. The Friday afternoon nursing session will feature a "This Is Your Life" case history.

Chicago

Summer Camp for Diabetic Children.—The Chicago Diabetes Association, announces its sixth summer camp for diabetic children, July 18-Aug. 8 at Holiday Home, Lake Geneva, Wis. There will be a staff of resident physicians and dietitians, trained in the care of diabetic children. Boys and girls, ages 8-14, are eligible. Fees will be set on a sliding scale to meet individual circumstances. Physicians are requested to notify parents of diabetic children and to supply the names of children who would like to attend camp. Information may be obtained from the Chicago Diabetes Association, 5 S. Wabash Ave., Chicago 3 (ANdover 3-1861). Limited capacity requires prompt application.

Dr. Sanford Succeeds Dr. Poncher.—Dr. Heyworth N. Sanford, acting head, department of pediatrics, University of Illinois College of Medicine since September, 1952, has been appointed head of the department succeeding Dr. Henry G. Poncher who resigned. Dr. Sanford, who has been a member of the faculty of the university since 1941 when he was

Physicians are invited to send to this department items of news of general interest, for example, those relating to society activities, new hospitals, education and public health. Programs should be received at least three weeks before the date of meeting.

appointed clinical associate professor of pediatrics, was promoted to full professor in 1944. He received Raymond B. Allen instructorship awards from both the senior and junior classes in medicine last June. Dr. Sanford has resigned positions as chairman of the department of pediatrics at Presbyterian Hospital and as president of the medical staff of that institution but will continue his association with Cook County Hospital, with which he has been affiliated since 1930 and where, during the past seven years, he has been head of the department of children's hematology and attending physician.

MARYLAND

Dr. Cooley Goes to Texas.—Dr. Robert N. Cooley, assistant professor of radiology, Johns Hopkins University School of Medicine, Baltimore, has accepted appointment as professor of radiology and chairman of the department at the University of Texas Medical Branch, Galveston. An extension of department facilities in the new John Sealy Hospital building is being developed under Dr. Cooley's direction.

Society News.—At a meeting March 19, 8:30 p. m., in Osler Hall, 1211 Cathedral St., the Baltimore City Medical Society will present a panel discussion "Uses and Abuses of ACTH and Cortisone" with Dr. A. McGehee Harvey, director, department of medicine, Johns Hopkins University School of Medicine, as moderator. Participants will be Dr. Joseph L. Hollander, director, department of medicine, University of Pennsylvania School of Medicine, Philadelphia, and Drs. Lawrence E. Shulman, assistant in medicine, Alan C. Woods, professor of ophthalmology, Leslie N. Gay, associate professor of medicine, and Raymond C. V. Robinson, instructor in medicine, Johns Hopkins University School of Medicine.

MICHIGAN

County Secretaries-Public Relations Conference.—At the annual County Secretaries-Public Relations Conference, Jan. 31, in Detroit, Dr. L. Dell Henry, Ann Arbor, served as chairman of the conference. Dr. L. Fernald Foster, Bay City, was chairman of discussions incident to the presentation of nine dramatic skits, entitled "What Would You Do?" in which the following practical problems faced by county society secretaries were portrayed: 1. How Long Should a County Medical Society Secretary Serve? 2. Membership Problems. 3. Orientation of New Members. 4. Enforcement of Mediation. 5. Utilization of Hospital and Medical Care Insurance. 6. Importance of Office Secretary to M.D. 7. Itemized Bills. 8. M.D. Participation in Civic Affairs. 9. Solicitation of Ex-Members. Dr. C. Allen Payne, Grand Rapids, was chairman of the Public Relations Conference, at which the following program was presented:

Operation Periphery, Mr. Edgar L. Harden, East Lansing.

Deekside PR, John F. Conlin, Boston.

How Well Do You Know Your Business? Mr. L. Clayton Hill, Ann Arbor.

Here's the Score for '54, C. Allen Payne, Grand Rapids, and Mr. Hugh W. Brennehan, Lansing.

MISSOURI

Society News.—Under the sponsorship of the St. Louis Society for Internal Medicine, Dr. William Dock, professor of medicine, State University of New York College of Medicine at New York City, Brooklyn, will present "Causes and Significance of Apical Localization of Tuberculosis" at a meeting of the St. Louis Medical Society, March 16, 8:30 p. m., in the medical society auditorium, 3839 Lindell Blvd.

Study of Infant Mortality.—A committee to study the infant mortality in the hospitals of St. Louis and St. Louis County has been formed as a joint organization of the St. Louis Academy of General Practice, the St. Louis Gynecology Society, and the St. Louis Pediatric Society. Recently published figures of the St. Louis health commissioner, Dr. J. Earl Smith, show that the death rate among infants in St. Louis has risen each year since 1949 and that the city now has the highest infant death rate of all the large cities. The committee will analyze each infant death in all hospitals of the city and county of St. Louis.

NEW JERSEY

Cardiac Seminar.—The New Jersey Heart Association has scheduled its fifth scientific session for March 17, 2-5:30 p. m. in the auditorium, Mutual Benefit Life Insurance Company, 300 Broadway, Newark. The program will include:

Rotational Effects on the ECG, Simulating Myocardial Infarction, Emanuel Goldberger, New York.

Modern Ballistocardiography, Benjamin M. Baker and Martin L. Singewald, Baltimore.

Clinical Significance of Heart Sounds, J. Scott Butterworth, New York.

Choice of Anesthesia for the Cardiac Patient, Leroy D. Van Dam, Philadelphia.

Ectopic Rhythms Secondary to Electrolyte Imbalance, Samuel Bellet, Philadelphia.

Indications for Cardiac Surgery, Ferdinand F. McAllister, New York.

NEW YORK

Society News.—On March 18, 9 p. m., Dr. Leo H. Crip, associate professor of medicine, University of Pittsburgh School of Medicine, will present "Vascular Allergy" before the section on allergy, Medical Society of the County of Kings and Academy of Medicine of Brooklyn, 1313 Bedford Ave., Brooklyn.

New Director of Saranac Laboratory.—Dr. Gerrit Willem Hendrik Schepers of Johannesburg, South Africa, has been named director of the Saranac Laboratory of the Trudeau-Saranac Institute in Trudeau. Dr. Schepers was formerly affiliated with the Medical School, Johannesburg, the Johannesburg Municipal Benefit Society, for which he was administrative and research medical officer, and the Medical Faculty of Pretoria. He is chairman of the pulmonary disability committee of the Miner's Phthisis Bureau and was awarded the Queen's Coronation medal in recognition of his service in the field of pulmonary disease disability.

New York City

Tumor Clinic.—Dr. John J. Conley, assistant surgeon, Manhattan Eye, Ear and Throat Hospital, and associate surgeon, otolaryngology, St. Vincent's Hospital, will discuss "Cancer of the Cervical Esophagus with Immediate One Stage Repair" at the Tumor Clinic Conference, Harlem Hospital, March 17, 10:45 a. m.

Harvey Lecture.—Albert L. Lehninger, Ph.D., DeLamar professor of physiological chemistry and director of the department of physiological chemistry, Johns Hopkins University School of Medicine, Baltimore, will present "Oxidative Phosphorylation," the seventh Harvey lecture of the 1953-1954 series, at the New York Academy of Medicine, March 18.

Talk on Medical Jurisprudence.—The Omicron chapter of the Phi Delta Epsilon fraternity at New York Medical College will hold the annual Aaron Brown lectureship, March 17. Judge Julius Isaacs, chairman of the committee on medical jurisprudence of the New York Bar Association, will discuss "A Survey of the Position of the Doctor and Law."

Rehabilitation Workshop.—Columbia University Teachers College and Institute for the Crippled and Disabled will hold a three and one-half week field workshop in rehabilitation teamwork, beginning June 1. A maximum of 35 professionals experienced in their own disciplines will be admitted to the course, which will include field experience, rehabilitation seminars, daily case conferences, individual counseling, and guest lectures. Fee for the course, \$100, includes \$75 for tuition, \$7 Columbia University fee, and \$18 to cover the cost of books, syllabuses, pamphlets, and mimeographed material. Applications must be filed before April 1. Information may be obtained from Maurice A. Fouracre, Teachers College, Columbia University, New York 27.

OHIO

Cancer Research Laboratory.—The new five-story cancer research laboratory wing to the University Hospital at Ohio State University Health Center, Columbus, was recently constructed with funds appropriated by the state legislature, plus a matching research construction grant from the National Cancer Institute of the U. S. Public Health Service and a supple-

mental grant from the Kettering Research Foundation. The first floor houses the Columbus Cancer Clinic, a continuation of the first free diagnostic cancer clinic opened in this country in 1921. Research studies at the clinical level will be followed here, where the cancer registry and special research records and files will be kept. Research laboratories occupy all other floors. The second floor, known as the Herman A. Hoster Research Laboratories, has facilities for a continuation of the enzyme and biochemical studies on Hodgkin's and allied diseases, which were intensively pursued under the direction of the late Dr. Hoster, who was instrumental in obtaining the new

Cancer Research Laboratory.

wing. The third floor has 12 research laboratories. The fourth floor has the air-conditioned small animal quarters and laboratories for medical biophysics, including radioactive isotope investigations. The basement level has a cold room, a deep freeze room, and the cancer research laboratories for the department of obstetrics and gynecology.

OKLAHOMA

Practitioners' Conferences.—Through the Postgraduate Instruction Program made available to the physicians of Oklahoma by the office of postgraduate instruction at the University of Oklahoma School of Medicine, Oklahoma City, the following conferences will be held at the auditorium in the school of medicine at 7:30 p. m.: March 18, atopic dermatitis; April 15, poliomyelitis; and May 20, diagnosis and treatment of congestive failure.

Tape Recordings Available.—The Council of the Oklahoma State Medical Association has approved a new, nonprofit, medical tape recording library. Many important meetings and postgraduate courses in Oklahoma for the past year have been recorded, and it is contemplated that several national meetings

will be tape-recorded by this service. Recordings are distributed by the Srigley-Randels Clinic, Hollis. A nominal rental fee is charged to cover operating costs. Other medical recording libraries in operation are the SOS GP Library, 286 W. McMicken Ave., Cincinnati 14, Ohio, and Audio-Digest 404 E. Broadway, Glendale, Calif. Almost 40 tapes are now available through request to the executive office or to Dr. Robert S. Srigley, Hollis.

PENNSYLVANIA

Meeting on Physical Medicine.—The Pennsylvania Academy of Physical Medicine and Rehabilitation will present the following program March 20 at Valley Forge Army Hospital, Phoenixville:

Clinical Electromyography, Lieut. Col. Edward B. Shires, Phoenixville; discussed by Francis J. Bonner, Ardmore.

Pain Threshold, Capt. Thomas Guthrie, Collegeville; discussed by Herman L. Rudolph, Reading.

Physical Medicine in the Treatment of Preoperative and Postoperative Chest Surgery Patients, Lieut. Robert M. Krout, New Cumberland; discussed by William H. Schmidt, Philadelphia.

Physical Medicine in the Treatment of Hand Surgery Patients, Lieut. Sidney Barr, Philadelphia; discussed by Harold Lefkoe, Philadelphia.

(Note: To reach the hospital, turn onto Bridge St. in Phoenixville at a three-way intersection from Pennsylvania routes 23 and 83 and drive about a half-mile southwest of Phoenixville.)

TEXAS

Dr. Guthrie of Scotland to Lecture in Galveston.—Dr. Douglas Guthrie, medical historian of the University of Edinburgh, who is visiting medical centers in the United States, after a tour of Australia and New Zealand, will give the address "The Pursuit of the Infinitely Small," which deals with the history of the microscope, at the University of Texas Medical Branch, Galveston, March 19. He will also present a special lecture on "Ancient Drugs and Herbals." Dr. Guthrie will deliver the Logan Clendening lectures at the University of Kansas, Lawrence and Kansas City, Kan., March 29-31.

Clinical Conference.—The Dallas Southern Clinical Society will hold its annual clinical conference March 15-18 at the society headquarters in the Medical Arts Building. Guest speakers include Drs. Willard M. Allen and Charles H. Eyermann, St. Louis; Drs. William B. Bean and Alson E. Braley, Iowa City; Dr. Edward G. Billings, Denver; Dr. William L. Bradford, Rochester, N. Y.; Drs. Ormond S. Culp and Thomas J. Dry, Rochester, Minn.; Dr. Clarence Dennis, Brooklyn; Dr. Hugh F. Hare, Los Angeles; Dr. Anderson C. Hilding, Duluth; Dr. Samuel F. Marshall, Boston; Dr. Paul E. McMaster, Beverly Hills, Calif.; Dr. George T. Pack, New York; Dr. John L. Parks, Washington, D. C.; Dr. Douglas H. Sprunt, Memphis, Tenn.; Dr. C. Dwight Townes, Louisville, Ky.; and Dr. Walter P. Work, San Francisco. In addition to their individual presentations, the guests will participate in panel discussions on recent developments in cancer, diabetes, emotional problems of the menopause, respiratory problems of the newborn period, diagnosis and treatment of benign breast lesions, cardiac catheterization, drug allergies, internal versus external fixation of fractures, and complications of labor.

WISCONSIN

Harris Obstetrical Society.—The John Warton Harris Obstetrical Society was organized Sept. 5-6, 1953, by former residents trained by Dr. John W. Harris, professor of obstetrics and gynecology, University of Wisconsin Medical School, and chairman, department of obstetrics and gynecology, Wisconsin General Hospital, Madison. Membership is limited to residents trained by Dr. Harris and members of his department. The following officers were elected: president, Dr. Madeline J. Thornton, Madison, president-elect, Dr. E. Russell Muntz, Ada, Okla., and secretary-treasurer, Dr. Alice D. Watts, Milwaukee.

State Society Offers Postgraduate Courses.—The Medical Society of the State of Wisconsin presents a series of postgraduate courses in cooperation with the Wisconsin State Board of Health, University of Wisconsin Medical School, Marquette University School of Medicine, Wisconsin Academy of Gen-

eral Practice, Wisconsin Heart Association, Wisconsin division, American Cancer Society, Wisconsin Anti-Tuberculosis Association, and the Wisconsin chapter, American Arthritis and Rheumatism Foundation. In March Dr. Robert C. Parkin, director of postgraduate education, University of Wisconsin Medical School, Madison, will serve as moderator for the following program, which will be held from 2 to 5:30 p. m., March 16 in Monroe (Turner Hall), March 17 in Kenosha (Elks Club), and March 18 in Portage (Elks Club):

Problems of Growth, Including Adolescence, Thomas V. Geppert, Madison.

Management of Cardiovascular Problems, Mischa J. Lustok, Milwaukee. Diagnosis and Treatment of Vaginitis and Cancer of the Cervix, Edward D. Allen, Chicago.

Early Management of the Acute Head Injury, Alfred Uihlein, Rochester, Minn.

The April program in Eau Claire, Stevens Point, and Appleton will feature related diseases of the chest, and in Platteville, Oconomowoc, and Manitowoc, child nutrition, ankle fractures, maternal mortality, and diabetes. Each program will be followed by dinner and an evening session. Reservations (\$6 including dinner for each clinic) may be made through the State Medical Society of Wisconsin, Box 1109, Madison.

GENERAL

Deadline for Radiology Examinations.—The American Board of Radiology announces that May 1 is the deadline for filing applications for the fall examination, which will be held during the week of Sept. 13 in Washington, D. C.

Memorial Volume.—The *Journal of Neuropathology and Experimental Neurology* issues its January number as a memorial volume to Dr. Joseph H. Globus, New York, one of its founders, who was executive editor for 11 years. Dr. Globus, who was born in Russia, came to New York and was graduated from Cornell University Medical College. After World War I, in which he served as captain in the Medical Corps, U. S. Army, he was awarded the Blumenthal Research Fellowship at Mount Sinai Hospital with which he was affiliated until his death Nov. 19, 1952.

College of Physicians Postgraduate Courses.—The American College of Physicians has announced its spring postgraduate courses. A course in clinical gastroenterology is scheduled at Louisiana State University School of Medicine, New Orleans, March 15-19. The guest faculty includes: Dr. David Cayer, Winston-Salem, N. C., Dr. Donald F. Marion, Miami, Fla., Dr. Eddy D. Palmer, Washington, D. C., Dr. H. Marvin Pollard, Ann Arbor, Mich., and Dr. Julian M. Ruffin, Durham, N. C. March 22-26, selected subjects in internal medicine will be offered at the Columbia-Presbyterian Medical Center, New York, with Drs. Franklin M. Hanger and Robert F. Loeb as co-directors; fees are \$30 for college members and \$60 for non-members.

Southern States' Special Train to San Francisco.—Announcement is made of the "Southern A. M. A. Special" tour for physicians and their families to the American Medical Association's meeting in San Francisco, June 21-25. The 8,000 mile tour includes the Canadian Rockies, California, and Mexico, a 20-day vacation with 5 days in San Francisco for the convention. The tour, which leaves Atlanta at 10 a. m. June 13 and returns to Atlanta at 8:35 a. m. July 2, will cost \$445 (plus tax). It includes stops in New Orleans, San Antonio, Texas, Juarez, Mexico, and the Grand Canyon. The post-convention itinerary includes Seattle, Vancouver, B. C., and Banff and Lake Louise in the Canadian Rockies. Information may be obtained from Moyers Travel Bureau at the Bank of Georgia, 34-38 Peachtree St., Atlanta.

Fellowship in Dermal Pathology.—The Earl D. Osborne fellowship in dermal pathology, sponsored by the American Academy of Dermatology and Syphilology, will provide annually for one year the opportunity for study and training in dermal pathology to a postgraduate student who has completed satisfactorily at least two years of training in dermatology or one of its allied branches in accordance with the requirements of the American Board of Dermatology and Syphilology. A stipend of \$2,500 will be given to the candidate selected. The

period of training, which will be accredited by the board, will be spent at the Armed Forces Institute of Pathology, Washington, D. C. Dermatologists in training may obtain application blanks for the fellowship from Dr. Hamilton Montgomery, Chairman, Committee on Pathology, American Academy of Dermatology and Syphilology, 102-110 Second Ave., S. W., Rochester, Minn. The next appointment available begins July 1.

Surgeons Meet at French Lick.—A sectional meeting of the American College of Surgeons will be held at the French Lick Springs Hotel, French Lick, Ind., March 15-17. A session dealing with causes of suits for malpractice and methods for their prevention has been scheduled, as has a clinicopathological conference with symposiums on trauma and cancer, and panel discussions on evaluation of gynecological procedures, intestinal obstruction, nutrition and preoperative and postoperative care in the aged, and indications for and operative methods in the open treatment of fractures. The program of the dinner meeting Monday will include the address "Thinkin' Tall" by Kenneth McFarland, Ph.D., Topeka, Kan., educational consultant, General Motors. Those interested in accommodations on a special train from Chicago, arriving at French Lick on Saturday, should communicate with Miss Eunice Morrill, American College of Surgeons, 40 E. Erie St., Chicago 11 (MOhawk 4-4050).

Fellowships in Psychiatric Care of the Disabled.—The National Foundation for Infantile Paralysis has a number of fellowships available to psychiatrists interested in the emotional problems of the physically disabled, particularly of the poliomyelitis patient with respiratory paralysis. Requirements include two years of graduate training in psychiatry acceptable to the American Board of Psychiatry and Neurology. Financial benefits are based on individual needs. Appointments will be made for one year, subject to renewal. The programs of the fellows should be undertaken in a center concerned with rehabilitation of the physically disabled, which has affiliations with an approved department of psychiatry. The department is to be responsible for supervision and training of the fellows. An opportunity for working with poliomyelitis patients with respiratory difficulties should be available. For information and application forms write: Division of Professional Education, National Foundation for Infantile Paralysis, 120 Broadway, New York 5.

American Radium Society.—The annual meeting of the American Radium Society will be held at the Homestead, Hot Springs, Va., March 14-16. The Monday morning session will open at 9 a. m. with a symposium on cancer of the lung, for which Dr. Paul E. Rekers, Los Angeles, will serve as moderator and Drs. Samuel H. Rosen, Washington, D. C., John L. Pool, New York, Theodore P. Eberhard, Philadelphia, and Thomas Watson, as collaborators. The Janeway lecture, "Education in Radiation Protection," will be delivered by Lauriston S. Taylor, Ph.D., chief, Atomic and Radiation Physics Division, National Bureau of Standards, Washington, D. C., during the luncheon session, 12:15-2:15 p. m. The annual banquet will be held at 7 p. m. The Tuesday symposium (9 a. m.) on treatment of nasopharyngeal neoplasms will have as moderator Dr. Douglas Quick, New York, and as collaborators Drs. Higdon B. Elkins, Iowa City, Clifford L. Ash, Toronto, Canada, James W. J. Carpender, Chicago, Isadore Lampe, Ann Arbor, Mich., and Robert J. Bloor, Rochester, N. Y.

Kimble Methodology Research Award.—The University of Washington School of Medicine, Seattle, invites nominations before May 15 for the third Kimble methodology research award, which will be presented in October 1954 through the generosity of the Kimble Glassware Division of Owens-Illinois Co. The award, consisting of \$500 and a plaque, is administered by committees of the Conference of State and Provincial Public Health Laboratory Directors. Names of candidates from the United States, its territories, and Canada may be submitted. The candidate's work should be either a fundamental contribution that serves as a base line for development of diagnostic methods that fall within the province of the public health laboratory or the adaptation of a fundamental contribution to make it of use in a diagnostic laboratory. The work should

MEETINGS

have been completed since Jan. 1, 1949. Consideration will be given to nominations only if they are covered by (1) a reprint or a summary with bibliography and (2) a statement of the considerations that justified the recommendations of the study. Nominations should be sent to Alfred S. Lazarus, Ph. D., Chairman, School of Medicine, University of Washington, Seattle 5.

Conference on Chronic Illness.—The National Conference on Care of the Long-Term Patient will be held at the Edgewater Beach Hotel, Chicago, March 18-20, under the auspices of the Commission on Chronic Illness and the sponsorship of the American Medical Association, the American Hospital Association, the American Public Health Association, the American Public Welfare Association, and the U. S. Public Health Service. Mr. Leonard W. Mayo, commission chairman, will give the keynote speech Thursday, 10 a. m., after which conference orientation will be given by Dr. Dean W. Roberts, Baltimore, director of the commission. The following committees will coordinate the findings of the 20 discussion groups which will hold simultaneous meetings:

Committee I, The Patient at Home, Chairman, Dr. Martin Cherkasky, New York.

Committee II, The Patient in an Institution, Chairman, Anthony J. J. Rourke, New York.

Committee III, Integration of Facilities and Services, Chairman, Milton Terris, Buffalo.

Committee IV, Research, Chairman, Thomas Parran, Pittsburgh.

Committee V, Financing, Chairman, Theodore G. Klumpp, New York.

The reports of the five committee chairmen, combining the discussion group reports, will be presented from 11:15 a. m. to 1 p. m. Saturday. On Thursday at 7 p. m. Dr. Edwin S. Hamilton, Kankakee, Ill., vice-chairman of the commission, will preside at the banquet, after which the following will speak for their associations: Dr. George F. Lull, Chicago, (American Medical Association); Dr. Edwin L. Crosby, Chicago, (American Hospital Association); Dr. Herman E. Hilleboe, Albany, N. Y., (American Public Health Association); Miss Loula Dunn, (American Public Welfare Association); and Dr. Leonard A. Scheele, Washington, D. C., (U. S. Public Health Service).

FOREIGN

Otorhinolaryngologists Meet in Düsseldorf.—The 25th annual meeting of the German Society of Otorhinolaryngologists will be held June 2-5 in Düsseldorf. The subjects for discussion will be "Accidental Injuries of Nose and of Nasal Sinuses" and "Hearing Aids."

Centennial Celebrations in Germany.—The 100th anniversaries of the birth of two German Nobel prize winners, Dr. Paul Ehrlich and Dr. Emil von Behring, will be observed March 13-16 in Frankfurt-on-the-Main and in Marburg-Lahn, Germany. Dr. Ehrlich, who discovered arsphenamine (Salvarsan) in 1909, and Dr. von Behring, whose work in passive immunization laid the foundation for serum therapy and protective inoculation, will be honored at the commemorative services in St. Paul's Cathedral in Frankfurt. The Paul Ehrlich prize will be conferred on Prof. Ernst Boris Chain, in 1945 co-winner with Sir Alexander Fleming and Sir Howard Florey of the Nobel prize for physiology and medicine for the discovery of penicillin. Dr. Chain, formerly of Oxford University and presently scientific director of the International Research Centre for Chemical Microbiology in Rome, Italy, will speak on the development of antibiotic chemotherapy. The celebration will terminate with a scientific meeting in Höchst, in which several hundred physicians, chemists, and other scientists of European and overseas countries will participate.

CORRECTION

American College of Physicians.—In the list of meetings in THE JOURNAL, Feb. 27, page 775, the announcement of the meeting for the American College of Physicians was erroneous. This organization will meet in Chicago, April 5 to 9, at the Conrad Hilton Hotel. Mr. E. R. Loveland, 4200 Pine Street, Philadelphia 4, is the executive secretary.

AMERICAN MEDICAL ASSOCIATION; Dr. George F. Lull, 535 North Dearborn St., Chicago 10, Secretary.

1954 Annual Meeting, San Francisco, June 21-25.

1954 Clinical Meeting, Miami, Florida, Nov. 30-Dec. 3.

1955 Annual Meeting, Atlantic City, N. J., June 6-10.

1955 Clinical Meeting, Boston, Nov. 29-Dec. 2.

1956 Annual Meeting, Chicago, June 11-15.

AERO MEDICAL ASSOCIATION, Hotel Statler, Washington, D. C., March 29-31. Dr. Thomas H. Sutherland, P. O. Box 26, Marion, Ohio, Secretary.

ALABAMA, MEDICAL ASSOCIATION OF THE STATE OF, Mobile, April 15-17. Dr. Douglas L. Cannon, 537 Dexter Ave., Montgomery, Secretary.

AMERICAN ACADEMY OF GENERAL PRACTICE, Cleveland, March 22-25. Mr. Mac F. Cahal, 406 West 34th St., Kansas City 2, Mo., Executive Secretary.

AMERICAN ACADEMY OF NEUROLOGY, Shoreham Hotel, Washington, D. C., April 29-May 1. Dr. Alexander T. Ross, 1040 West Michigan St., Indianapolis 7, Secretary.

AMERICAN ASSOCIATION OF ANATOMISTS, Hotel Galvez, Galveston, Texas, April 7-9. Dr. Normand L. Hoerr, 2109 Adelbert Road, Cleveland 6, Secretary.

AMERICAN ASSOCIATION OF THE HISTORY OF MEDICINE, Hotel Taft, New Haven, Conn., May 6-8. Dr. Samuel X. Radbill, 7043 Elmwood Ave., Philadelphia 42, Secretary.

AMERICAN ASSOCIATION OF IMMUNOLOGISTS, Ambassador Hotel, Atlantic City, N. J., April 11-15. Dr. John Y. Sugg, 1300 York Ave., New York, Secretary.

AMERICAN ASSOCIATION OF PATHOLOGISTS AND BACTERIOLOGISTS, Philadelphia, Pa., April 8-10. Dr. Alan R. Moritz, 2085 Adelbert Road, Cleveland 6, Secretary.

AMERICAN ASSOCIATION OF RAILWAY SURGEONS, Drake Hotel, Chicago, April 6-8. Dr. Chester C. Guy, 5800 Stony Island Ave., Chicago 37, Secretary.

AMERICAN ASSOCIATION FOR THE STUDY OF NEOPLASTIC DISEASES, Lord Baltimore Hotel, Baltimore, April 29-30. Dr. Bruce H. Sisler, P. O. Box 268, Gatlinburg, Tenn., Executive Secretary.

AMERICAN ASSOCIATION FOR THORACIC SURGERY, Sheraton-Mt. Royal Hotel, Montreal, Canada, May 3-5. Dr. Paul C. Samson, 2938 McClure St., Oakland 9, Calif., Secretary.

AMERICAN COLLEGE OF ALLERGISTS, Roney Plaza Hotel, Miami Beach, Fla., April 5-10. Dr. Fred W. Wittich, 423 LaSalle Medical Bldg., Minneapolis 2, Secretary.

AMERICAN COLLEGE OF PHYSICIANS, Conrad Hilton Hotel, Chicago, April 5-9. Mr. E. R. Loveland, 4200 Pine St., Philadelphia 4, Executive Secretary.

AMERICAN DERMATOLOGICAL ASSOCIATION, The Greenbrier, White Sulphur Springs, W. Va., April 13-17. Dr. J. Lamar Callaway, Duke Hospital, Durham, N. C., Secretary.

AMERICAN FEDERATION FOR CLINICAL RESEARCH, Haddon Hall, Atlantic City, N. J., May 2. Dr. Lawrence E. Hinkle Jr., 525 East 68th St., New York 21, Secretary.

AMERICAN GOUTER ASSOCIATION, The Somerset, Boston, April 29-May 1. Dr. John C. McClintock, 149½ Washington Ave., Albany 10, N. Y., Secretary.

AMERICAN HEART ASSOCIATION, Conrad Hilton Hotel, Chicago, April 1-4. Dr. William H. Bunn, 44 East 23d St., New York 10, Secretary.

AMERICAN PEDIATRIC SOCIETY, The Inn, Buck Hill Falls, Pa., May 3-5. Dr. A. C. McGuinness, 237 Medical Laboratories, University of Pennsylvania, Philadelphia 4, Secretary.

AMERICAN PHYSIOLOGICAL SOCIETY, Ambassador Hotel, Atlantic City, N. J., April 10-16. Dr. Milton O. Lee, 2101 Constitution Ave., Washington 25, D. C., Executive Secretary.

AMERICAN PSYCHIATRIC ASSOCIATION, St. Louis, May 3-7. Dr. R. Finley Gayle Jr., 6300 Three Chopt Road, Richmond 21, Va., Secretary.

AMERICAN PSYCHOSOMATIC SOCIETY, Jung Hotel, New Orleans, March 27-28. Dr. Theodore Lidz, 333 Cedar St., New Haven 11, Conn., Secretary.

AMERICAN RADIUM SOCIETY, The Homestead, Hot Springs, Va., March 14-16. Dr. Robert E. Fricke, 102 Second Ave. S.W., Rochester, Minn., Secretary.

AMERICAN SOCIETY OF BIOLOGICAL CHEMISTS, Atlantic City, N. J., April 12-16. Dr. Philip Handler, Duke University, Durham, N. C., Secretary.

AMERICAN SOCIETY FOR CLINICAL INVESTIGATION, Haddon Hall, Atlantic City, N. J., May 3. Dr. William M. Kirby, Univ. of Washington School of Medicine, Seattle 5, Secretary.

AMERICAN SOCIETY FOR EXPERIMENTAL PATHOLOGY, Atlantic City, N. J., April 12-16. Dr. Cyrus C. Erickson, 874 Union Ave., Memphis 3, Tenn., Secretary.

AMERICAN SOCIETY OF MAXILLOFACIAL SURGEONS, Washington, D. C., April 25-28. Dr. Casper M. Epstein, 25 East Washington St., Chicago 2, Secretary.

AMERICAN SOCIETY FOR PHARMACOLOGY AND EXPERIMENTAL THERAPEUTICS, Atlantic City, N. J., April 12-16. Dr. Carl C. Pfeiffer, 1853 West Polk St., Chicago 12, Secretary.

AMERICAN SURGICAL ASSOCIATION, Hotel Cleveland, Cleveland, April 28-30. Dr. R. Kennedy Gilchrist, 59 East Madison St., Chicago 3, Secretary.

ARIZONA MEDICAL ASSOCIATION, San Marcos Hotel, Chandler, April 25-28. Dr. Dermont W. Melick, 541 Security Bldg., Phoenix, Secretary.

ARKANSAS MEDICAL SOCIETY, Goldman Hotel, Fort Smith, April 19-21. Dr. J. J. Monfort, 215 Kelley Bldg., Fort Smith, Secretary.

ASSOCIATION OF AMERICAN PHYSICIANS, Chalfonte-Haddon Hall, Atlantic City, N. J., May 4-5. Dr. W. Barry Wood Jr., 600 S. Kingshighway Blvd., St. Louis 10, Secretary.

CONFERENCE ON MICROCIRCULATORY PHYSIOLOGY AND PATHOLOGY, University of Texas, Galveston, Texas, April 8-9. Dr. Edward H. Bloch, Western Reserve University School of Medicine, Dept. of Anatomy, Cleveland 6, Chairman.

CONNECTICUT STATE MEDICAL SOCIETY, Bulkeley High School, Hartford, April 27-29. Dr. Creighton Barker, 160 St. Ronan St., New Haven, Executive Secretary.

DALLAS SOUTHERN CLINICAL SOCIETY, Dallas, March 15-18. Dr. T. Haynes Harvill, 433 Medical Arts Bldg., Dallas 1, Texas, Secretary.

EASTERN SECTION, AMERICAN CONGRESS OF PHYSICAL MEDICINE, Newark, N. J., April 10. Dr. H. L. Rudolph, 400 North Fifth St., Reading, Pa., Secretary.

EASTERN STATES HEALTH EDUCATION CONFERENCE, New York Academy of Medicine, New York, April 29-30. Dr. Iago Galdston, 2 East 103d St., New York 19, Secretary.

EASTERN SURGICAL SOCIETY, Boston, March 26-27. Dr. J. William Hinton, 130 East 79th St., New York, Secretary.

FEDERATION OF AMERICAN SOCIETIES FOR EXPERIMENTAL BIOLOGY, Convention Hall, Atlantic City, N. J., April 12-16. Dr. M. O. Lee, 2101 Constitution Ave., Washington 25, D. C., Secretary.

FLORIDA MEDICAL ASSOCIATION, Hollywood Beach Hotel, Hollywood, April 25-28. Dr. Samuel M. Day, P. O. Box 1018, Jacksonville, Secretary.

GEORGIA MEDICAL ASSOCIATION OF, Hotel Dempsey and Macon Auditorium, Macon, May 2-5. Dr. David H. Poer, 875 West Peachtree St. N.E., Atlanta, Secretary.

INDUSTRIAL HEALTH CONFERENCE, Hotel Sherman, Chicago, April 24-30. Dr. E. C. Holmblad, 28 East Jackson Blvd., Chicago 4, Managing Director.

INDUSTRIAL MEDICAL ASSOCIATION, Hotel Sherman, Chicago, April 27-30. Dr. Arthur K. Peterson, 28 East Jackson Blvd., Suite 1300, Chicago 4, Secretary.

IOWA STATE MEDICAL SOCIETY, Des Moines, April 25-28. Dr. Allan B. Phillips, 529 36th St., Des Moines 12, Secretary.

ISTHMIAN CANAL ZONE, MEDICAL ASSOCIATION OF THE, El Panama Hotel, Panama City, R. P., March 24-26. Dr. I. Robert Berger, Box "A," Balboa Heights, Canal Zone.

JOHN A. ANDREW CLINICAL SOCIETY, Memorial Hospital, Tuskegee Institute, Ala., April 11-16. Dr. Eugene H. Doble Jr., John A. Andrew Memorial Hospital, Tuskegee Institute, Ala., Secretary.

KANSAS MEDICAL SOCIETY, Hotel Jayhawk, Topeka, May 2-6. Dr. D. D. Vermillion, 315 West Fourth St., Topeka, Secretary.

MARYLAND, MEDICAL AND CHIRURGICAL FACULTY OF THE STATE OF, Baltimore, April 27-28. Dr. Everett S. Diggs, 1211 Cathedral St., Baltimore, Secretary.

MISSOURI STATE MEDICAL ASSOCIATION, Hotel Jefferson, St. Louis, April 4-7. Dr. E. Royce Bohrer, 634 North Grand Blvd., St. Louis 3, Secretary.

NATIONAL CONFERENCE ON CARE OF THE LONG-TERM PATIENT, Edgewater Beach Hotel, Chicago, March 18-20. Dr. Dean W. Roberts, 615 N. Wolfe St., Baltimore 5, Director.

NORTH CAROLINA, MEDICAL SOCIETY OF THE STATE OF, Hotel Carolina, Pinehurst, May 3-5. Dr. Millard D. Hill, 203 Capital Club Bldg., Raleigh, Secretary.

NORTH DAKOTA STATE MEDICAL ASSOCIATION, Grand Forks, May 1-4. Mr. Lyle A. Limond, Box 1198, Bismarck, Executive Secretary.

OHIO STATE MEDICAL ASSOCIATION, Columbus, April 13-15. Mr. Charles S. Nelson, 79 East State St., Columbus 15, Executive Secretary.

PACIFIC NORTHWEST SOCIETY OF PATHOLOGISTS, Amphitheater, Dept. of Pathology, University of Washington School of Medicine, Seattle, April 23-24. Dr. John L. Whitaker, 315 South K St., Tacoma 3, Wash., Secretary.

PACIFIC NORTHWEST SOCIETY OF PLASTIC AND RECONSTRUCTIVE SURGEONS, Seattle, April 3. Dr. E. E. Banfield, Medical Arts Bldg., Tacoma 2, Wash., Secretary.

REGIONAL MEETINGS, AMERICAN COLLEGE OF PHYSICIANS: TOPEKA, KANS., March 19. Dr. William C. Menninger, 3617 West 6th Ave., Topeka, Kansas, Governor.

RHODE ISLAND MEDICAL SOCIETY, Rhode Island Medical Society Library, Providence, May 4-5. Dr. Thomas Perry Jr., 106 Francis St., Providence 3, Secretary.

SECTIONAL MEETINGS, AMERICAN COLLEGE OF SURGEONS:

FRENCH LICK SPRINGS, Indiana, French Lick Springs Hotel, March 15-17. Dr. Carl H. McCaskey, 20 N. Meridian St., Indianapolis 4, Chairman.

MONTREAL, CANADA, Mount Royal Hotel, March 31-April 2. Dr. Harry S. Morton, 900 Sherbrooke St., West, Montreal, Canada, Chairman.

SOCIETY OF AMERICAN BACTERIOLOGISTS, William Penn Hotel, Pittsburgh, May 2-7. Dr. John Hays Bailey, Sterling-Winthrop Research Institute, Rensselaer, N. Y., Secretary.

SOCIETY OF NEUROLOGICAL SURGEONS, The Waldorf Astoria, New York, April 23-24. Dr. Edgar F. Fincher, Emory University, Ga., Secretary.

SOCIETY FOR PEDIATRIC RESEARCH, Buck Hill Falls Inn, Buck Hill Falls, Pa., May 4-6. Dr. Sydney S. Gellis, 330 Brookline Ave., Boston 15, Secretary.

SOUTHEASTERN ALLERGY ASSOCIATION, Dinkler-Plaza Hotel, Atlanta, Ga., March 25-27. Dr. Katharine B. MacInnis, 1515 Bull St., Columbia 1, S. C., Secretary.

STUDENT AMERICAN MEDICAL ASSOCIATION, Sherman Hotel, Chicago, May 1-3. Mr. Russell F. Staudacher, 535 N. Dearborn St., Chicago 10, Executive Secretary.

TENNESSEE STATE MEDICAL ASSOCIATION, Nashville, April 18-21. Mr. V. O. Foster, 706 Church St., Nashville 3, Executive Secretary.

TEXAS MEDICAL ASSOCIATION, Gunter Hotel, San Antonio, May 3-5. Dr. J. M. Travis Sr., 1801 Lamar Blvd., Austin, Secretary.

UNITED STATES-MEXICO BORDER PUBLIC HEALTH ASSOCIATION, Albuquerque, N. Mex., April 6-9. Sidney B. Clark, 314 U. S. Court House, El Paso, Texas, Secretary.

WESTERN INDUSTRIAL MEDICAL ASSOCIATION, Hotel Biltmore, Los Angeles, May 8. Dr. Edward J. Zaik, 740 S. Olive St., Los Angeles 14, Secretary.

FOREIGN AND INTERNATIONAL

ASSOCIATION OF SURGEONS OF GREAT BRITAIN AND IRELAND, Leeds, England, May 13-15, 1954. Dr. Henry W. S. Wright, 45 Lincoln's Inn Fields, London W.C.2, England, Honorary Secretary.

BRITISH MEDICAL ASSOCIATION, Glasgow, Scotland, July 1-9, 1954. Dr. A. Macrae, B.M.A. House, Tavistock Square, London, W.C.1, England, Secretary.

CANADIAN MEDICAL ASSOCIATION, Vancouver, B. C., Canada, June 14-18, 1954. Dr. T. C. Routley, 244 St. George St., Toronto 5, Ontario, Canada, General Secretary.

CONFERENCE OF INTERNATIONAL UNION AGAINST TUBERCULOSIS, Madrid, Spain, Sept. 26-Oct. 2, 1954. Secretariat, Escuela de Tisiologia, Ciudad Universitaria, Madrid, Spain.

CONGRESS OF INTERNATIONAL ASSOCIATION FOR THE PREVENTION OF BLINDNESS, New York, N. Y., U. S. A., Sept. 12-17, 1954. Professor Franceschetti, 2 Avenue Mirmot, Geneva, Switzerland, Secretary-General.

CONGRESS OF INTERNATIONAL ASSOCIATION FOR THE STUDY OF THE BRONCHI, Geneva, Switzerland, June 5-6, 1954. Professor A. Montandon, Clinique Universitaire d. O.R.L., Hôpital Cantonal, Geneva, Switzerland, Chairman.

EUROPEAN SOCIETY OF CARDIOVASCULAR SURGERY, Edinburgh, Scotland, July 9-10, 1954. For information address: Mr. A. J. Slessor, Department of Surgery, University New Building, Edinburgh 8, Scotland.

HEALTH CONGRESS OF THE ROYAL SANITARY INSTITUTE, Scarborough, England, April 27-30, 1954. Mr. P. Arthur Wells, Royal Sanitary Institute, 90 Buckingham Palace Road, London, S.W.1, England, Secretary.

GOVERNMENT SERVICES

DEPARTMENT OF DEFENSE

Reserve Retirement Points Granted for Aeromedical Convention.—Reserve retirement point credits may be earned by Medical Service Reserve officers on inactive duty for attendance at the Annual Aero Medical Association meeting. This authorization covers eligible physicians, dentists, veterinarians, nurses, women's medical specialists, and Medical Service Corps officers of the U. S. Navy and Air Force. The meeting will open at 9 a. m., Monday, March 29, at the Statler Hotel, Washington, D. C. A three day program of scientific presentations and discussions will follow. Point credits will be awarded to eligible reserve officers on the basis of one point for each day of attendance, provided sessions attended total at least two hours. Each day of the meeting will be considered a session. Included among the subjects to be presented are the aeromedical aspects of jet transport aircraft, crew safety, and effectiveness aboard the new B-52 strategic bomber, noise and vibration problems, development of a personality test battery for psychiatric screening of flying personnel, stress factors affecting combat pilots in Korea, helicopter evacuation of battle casualties, and other topics pertinent to aviation medicine. The convention will be interspersed with two dinners, a business luncheon, and a luncheon for wives. Visiting specialists in aviation medicine will include representatives from Australia, Denmark, Great Britain, Italy, Sweden, Switzerland, and Thailand.

PUBLIC HEALTH SERVICE

Sanitary Engineering Center to Be Dedicated.—The six-story fireproof building in Cincinnati that will house the Sanitary Engineering Center of the U. S. Public Health Service will be dedicated by Mrs. Oveta Culp Hobby, Secretary of the Department of Health, Education, and Welfare, on April 8. The Sanitary Engineering Center, until recently the Environmental Health Center, is the focal point of the federal government's research on how health may be affected by contacts with elements found in air, water, and food, and by radiation and other environmental factors. The structure is located at Columbia Parkway and Grandin Road, about six miles east of downtown Cincinnati and overlooking the Little Miami River. It was authorized by the 80th Congress, in 1948.

The ceremony will be attended by a number of members of Congress who were concerned with the legislation authorizing the building and others who are members of congressional committees that deal with health and public works legislation. Leaders in the fields of sanitary engineering, the biological and physical sciences, public health, industry, and other allied professions from all of the states and territories, will be invited. Scientists from universities and other research institutions will also attend. Dr. Leonard Scheele, Surgeon General, Public Health Service, and Mr. Mark Hollis, Chief Engineering Officer, Public Health Service, will speak, and Mr. Vernon MacKenzie, Officer in Charge of the Sanitary Engineering Center, will be host for the occasion.

On the second day of the program, Oram Woolpert, director, Ohio State Research Foundation, Detlev W. Bronk, president, Rockefeller Institute for Medical Research, Gordon M. Fair, professor of sanitary engineering, Harvard University, and Herman E. Hilleboe, state health commissioner of New York and president of the American Public Health Association, will speak.

On the evening of April 8, at a banquet in the Netherland Plaza Hotel, Abel Wolman, a leading sanitary engineer, will discuss the significance of the new building and its research program.

The Public Health Service's Sanitary Engineering Center is the only laboratory in the nation to attempt a coordinated study of the health significance of physical, chemical and

biological forces in the environment. The program has steadily broadened in scope. To meet present needs the center is turning attention to problems of such water-borne virus diseases as infectious hepatitis; of water-borne toxins generated by algal growths; of hazardous chemicals in the water supply and in the atmosphere; of control of environmental radiation hazards that have been accentuated by the growth of the atomic energy industry; and to the development of rapid, automatic, and economical means for detecting and measuring contaminants in air and water by use of modern electronic techniques. Of particular interest is the center's training program for state and local health workers in advanced sanitation and radiological health subjects. During the past five years 160 training courses have been conducted, attended by more than 6,300 public health specialists from the 48 states and many foreign countries.

Prize for Malaria Research.—G. Robert Coatney, Ph.D., of the Public Health Service's National Institutes of Health, has been named the winner of the Darling Foundation prize for his work on malaria research. Dr. Coatney is head of the chemotherapy section of the laboratory of tropical diseases. He is a graduate of Iowa State University, where he received a doctorate in protozoology. Announcement of the award was made by the Geneva office of the World Health Organization. The prize was established in memory of Dr. Samuel T. Darling, who died in 1925 while making a malaria survey in the Near East for the League of Nations. Co-winner of the award was Prof. George MacDonald, director of the Ross Institute of Tropical Hygiene in London, England.

VETERANS ADMINISTRATION

Appoint Assistant Chief Medical Director.—Dr. Frank B. Brewer has been appointed assistant chief medical director in charge of operations for VA's 171 hospitals and domiciliaries, and 104 clinics to replace Dr. Robert C. Cook, who plans to retire because of ill health. Dr. Brewer will assume the task of coordinating and directing personnel, engineering, supply, patient administration, and other operational activities. He is a native of Tennessee, served in the Army Medical Corps from 1917 to 1920, and, then, became a surgeon with the U. S. Public Health Service. Transferring to the Veterans Bureau in 1921, he served in district offices and hospitals until 1924 when he became manager of the VA hospital at Boise, Idaho. He served successively as manager of VA hospitals at Livermore, Calif., Legion, Texas, and Oteen, N. C., from 1929 until 1946, when he became medical director of the former Atlanta, Ga., branch office. When the branch offices were closed in 1949, he became area medical director for the seven southeastern states. Dr. Brewer is a past president of the Grant County (N. Mex.) Medical Society and of the Southeastern Idaho Medical Society.

Fellowships in Cardiology and Hematology.—Two new fellowships have been established at the Veterans Administration Hospital, 42nd Ave. and Clement St., San Francisco, one a fellowship in cardiology beginning July 1 under the auspices of the San Mateo County Heart Association, the other a fellowship in hematology beginning the same date under the auspices of Stanford University Medical School and the National Institutes of Health. The stipend of either fellowship is \$300 per month. Appointments are for one year and will be renewable for an additional year. The applicant must be a graduate of a class A medical school. Preference will be given to candidates who have adequate previous training in clinical medicine. For information apply to Forrest M. Willett, M.D., chief, medical service.

FOREIGN LETTERS

BRAZIL

Diagnosis of Genitourinary Cancer by Cytological Examination.—In a paper read before the St. Luke's Medical Society of São Paulo, Drs. Melchior Sawaya, Dolirio Sandin, and Luiz Carlos de Almeida presented their studies on cytological examinations of urine sediment. They have made a positive diagnosis of cancer in 10 patients with tumors of the genitourinary tract. In each case the diagnosis was confirmed by clinical and radiological examination. From their experience, they conclude that (1) a thorough examination should be made of the centrifuged sediment of the urine if genitourinary cancer is suspected; (2) the urine must have been passed less than three hours prior to examination; (3) a cytological examination must always be made if the urine shows a large amount of blood (unless the cause is known to be nephritis, calculus, trauma, or hemorrhagic disease); (4) the cytological examination aids in differentiating between cancer, tuberculosis, and cyst of the urinary tract; (5) the cytological examination can reveal cancer cells of tumors of the prostate; (6) the cancer cells found in the urine sediment are apt to show degenerative changes because urine has physical and chemical properties harmful to the cells; (7) it is necessary to observe groups of cells or numerous cells and to study their nuclear characteristics, because of the possibility of completely vacuolized pseudocancer cells being present (the presence of such cells does not rule out cancer); (8) the absence of giant cells of tubercle does not rule out tuberculosis, because they are seldom found (it is necessary to find the tubercle bacilli to make a positive diagnosis of tuberculosis); (9) in patients with lymphosarcomatosis of the urinary tract in addition to the degenerative changes caused by urine, a greater number of nucleoli, mitoses, and hyperchromatic nuclei with more irregular distribution of the chromatin in relation to the smears of the material of the lymph node tumors obtained by aspiration were found; (10) the transitional multinucleated cells of the normal urinary tract must not be confused with the giant cells of tubercle; and (11) the cytological examination of urinary sediment may reveal pus cells, causative agents of infections, and eosinophilic reaction in the parasitic diseases.

ISRAEL

Coxsackie Virus.—According to a report of the Research Council of Israel, H. Bernkopf and S. Levine of the virus laboratory of the Hebrew University and the department of hygiene of the Israel Ministry of Health, succeeded in isolating Coxsackie viruses here. Coxsackie viruses were first isolated from patients during an epidemic of poliomyelitis. They have been recovered from flies and sewage in areas where poliomyelitis was prevalent. Both poliomyelitis and Coxsackie viruses have been isolated from the same patients. The latter have also been isolated from patients with "summer gripe," three day fever, influenza-like fever, and fever of unknown origin. The role of the Coxsackie viruses in all these diseases is not clear as yet. In two illnesses, however, herpangina and pleurodynia, evidence has been produced to show that Coxsackie viruses are the etiological agents. An immunologic study to determine the presence of antibodies to the Coxsackie viruses in sera collected from normal persons of various age groups was also carried out.

Fecal specimens from 111 patients with poliomyelitis have been studied. Ten strains of Coxsackie viruses were isolated, five from 65 patients with paralytic and five from 46 patients with nonparalytic infections. Fecal specimens from 80 patients with a variety of illnesses other than poliomyelitis yielded six strains of Coxsackie viruses. A study of the types of disease from which Coxsackie viruses were recovered revealed a high

percentage of virus isolations from infants whose condition was simply described as "dystrophia." Five of 19 such infants and one of the remaining 61 patients were found to excrete viruses in their stools.

A strain of Coxsackie virus was isolated from an outbreak diagnosed as pleurodynia that occurred in Naot Mordechai in September, 1950. Another strain was isolated during a similar outbreak in Kibbutz Maapil in March, 1951. Both strains belong to group B and appeared to be of the same type, on the basis of cross infection tests, and to have other properties in common. They are considered to be the etiological agents of the outbreaks.

Virus Related to West Nile Virus.—Bernkopf and Levine also reported that from July to September, 1951, a febrile disease in epidemic form occurred near Haifa. Both children and adults were attacked. Fever, symptoms pointing to meningeal involvement, and a rash were present in many of the children. In adults severe headache and general malaise were the main complaints. The temperature remained high for a few days only. Recovery was complete and more rapid in the children than in the adults. From the blood of a 14-year-old sick child a virus was isolated that was pathogenic for mice, hamsters, field mice, and chick embryos. It was filtrable through Seitz filters. Bacteriological examinations of infective material were always negative. A number of passages were carried out in both mice and eggs. In mice the virus was present in highest concentration in the brain. It was also found in the blood and other organs. On histological examination constant changes were present in the brain only, in which destruction of neurons and inflammatory changes were always found. No inclusion bodies could be demonstrated. Mice could be infected by various routes. In the egg the virus produced focal lesions on the membrane and ultimate death of the embryo. The virus was neutralized by antiserum against West Nile virus and, to a lesser degree, by antisera against Japanese B and St. Louis encephalitis viruses. Other antisera were without effect. Immune mice are resistant to intracerebral infection with at least 10^4 lethal doses of a strain of West Nile virus. The virus is closely related to or identical with West Nile virus. Neutralizing and complement fixing antibodies against the isolated strain developed during the disease in a number of patients.

New Physiotherapy and Dental Facilities.—A rehabilitation center, the first of its kind in the country, and including a physical therapy school, is being built at the Asaf Harofe Government Hospital in Sarafand. It will consist of prefabricated Finnish pavilions and will offer modern facilities for electrotherapy, hydrotherapy, occupational therapy, and orthopedic gymnastics to about 100 inpatients and about 120 outpatients. The latter will be able to spend several hours a day in the center. Most of the patients will be partly paralyzed children who have had poliomyelitis. The physical therapy school, which will train qualified physical therapists, also for the first time in this country, will be opened in January, 1954, in anticipation of the opening of the center next April. It will be headed by Miss D. B. Kidd, a British physical therapy specialist, sent to this country for two years by the World Health Organization. The new dental school at the Hebrew University was inaugurated in November, 1953. The first class is composed of 15 locally born young men and women. It is hoped that the goal—graduating classes of 30 each year—may be achieved in the near future.

Chloramphenicol.—The mode of action of chloramphenicol has recently been discussed by E. D. Bergmann and S. Sicher. Two points of attack have been suggested: interference with the utilization of phenylalanine, or with the synthesis of tryptophan from anthranilic acid via indole. In a wild strain of *Escherichia coli*, the inhibition caused by the antibiotic is reversed by tyrosine, phenylalanine, tryptophan, and indole,

but not by anthranilic acid. The synthesis of indole from anthranilic acid is thus the point of attack. This is confirmed by experiments with mutants of *Esch. coli*. The source of the lacking carbon atom that completes the molecule of anthranilic acid to the indole ring is methionine. In the wild strain of *Esch. coli*, the inhibition by chloramphenicol is reversed by the combination of anthranilic acid with methionine and vitamin B₁₂. Methionine has previously been found to be the source of the carbon atom of the purine nucleus and of the methyl group in nicotine. Anthranilic acid is not the immediate precursor of indole. It is first converted into another substance, the nature of which has not yet been determined.

ITALY

Renal Disease.—At the National Convention of Medicine in Rome, Bastai and Crepet supported the classification of nephropathies as (1) those due to decreased function of the arterioles (arteriolopathy), (2) glomerulitis or capillaritis, (3) inflammation of the tubules, and (4) interstitial nephropathy. They have considered the form due to inflammation of the arterioles a nephrosclerosis secondary to a process of hypertension. After a repeated and tenacious hypertensive spasm of the afferent artery, there is a diminution of the glomerular filtering capacity, and a parenchymal renal lesion ensues. Other forms of nephropathy due to inflammation of the arterioles are, besides those due to essential hypertension, those due to periarteritis nodosa, scleroderma, thromboangiitis obliterations, and symmetrical cortical necrosis. On this basis, the renal lesion that is seen in cases of benign or malignant essential hypertension is the consequence and not the cause of the hypertensive syndrome. This concept agrees with the latest works of Clifford Wilson at the University of London.

In two meetings held at the Royal College of Physicians in London in March, 1953, Professor Wilson proved, with his experiments on animals in parabiosis, that a vicious circle is established between the hypertension induced by adrenal cortical stimulation because of adrenal electrolytic imbalance (sodium, etc.) and the renal parenchymal alteration due to spasm of the afferent glomerular arteriole secondary to adrenocortical hypertension. Later, because of a decreased ability of the kidney to cleanse the blood from electrolytic elements that should be expelled, the adrenal cortex receives another impulse to increase the blood pressure, and as a result benign hypertension may change to malignant hypertension. The origin is not, however, in the renal lesion, which, as Clifford proved with his clinical experience, is a consequence of the hypertension and thereafter an aggravating rather than a causative factor. Without the interference of the adrenal, the renal disease would not cause hypertension. In fact, if a bilateral adrenalectomy is performed in an animal and if a parenchymal renal lesion is produced, hypertension does not develop. These interpretations refute the concept of a renal hypertensive factor (renin) as was assumed in the first studies of Goldblatt.

The speakers discussed nephropathies due to inflammatory capillaropathy among which they included hemorrhagic glomerulonephritis, proteinuric glomerulonephritis, renal amyloidosis, and those due to noninflammatory capillaropathy, among which they included diabetic nephropathy, nephropathy of pregnancy, simple arteriosclerotic nephropathy, and nephropathy due to myeloma. At the base there are always alterations of the capillary permeability of the glomerulus, whether these are acute or chronic inflammatory lesions, diffuse or localized. In other words, the glomerulonephritis can be acute or chronic, diffuse or localized. Genuine nephrosis also belongs to the group of the altered permeability of the glomerular capillary. In genuine nephrosis, which by many is attributed to a tubular defect, the proteinuria has always a glomerular cause.

In discussing this paper, Professor Poli asserted that true nephrosis is not a renal disease but a disease of the plasma protein. The altered condition of the plasma proteins in certain diseases causes a nephrosis that could occur also when the glomerulus is not damaged. According to Bastai and Crepet, the renal tubules are involved only in special manifestations of

a lack of reabsorption as for glucose in renal glycosuric diabetes, phosphorus in phosphaturic diabetes, etc. These are true nephropathies due to a primary abnormality of the tubules, but true nephrosis is not a primary disease of the tubules.

LONDON

Economical Prescribing.—A booklet has recently been published and distributed to all family doctors giving a list of the comparative cost of drugs in the National Health Formulary and equivalent proprietary preparations. The *British Medical Journal* of Oct. 24, 1953, included a letter on this subject. It is quoted below, together with certain editorial comments, and they give a picture of just one, more facet of the National Health Service that gives dissatisfaction. The matter has been considered by the General Medical Services Committee, which will discuss it with the Ministry of Health.

"During the past few years I have been trying to discipline myself to prescribe, and my patients to accept, various drugs by their standard names. This has involved the expenditure of some time and a lot of patients, but I imagined that this was worth while because it would save a considerable sum of money for the national Exchequer. Today I have been disillusioned and deflated. According to the list of costs posted to me today by the executive council I find that for many frequently prescribed drugs the proprietary drugs are cheaper than the standard equivalent, and my efforts have only increased the national drug bill.

"I am instructed that in future I must examine the list before writing any prescription and find out which is the cheapest preparation. In some cases, apparently, I must telephone the chemist to ask him whether he has opened a large or small pack of certain proprietary brands before I can decide the cost. I am further informed that arrangements are being made to find out easily whether I prescribe more economically from the list than my colleagues in the same area. I should like to know the estimated cost of the 'machinery' which will undertake this investigation.

"Directors of proprietary drug houses and the doctors who have prescribed their products have been pilloried in the National Press and higher places for a long time. They have been made the scapegoats of the rising national drug bill on entirely false premises.

"Is it not time we made a stand against all this nonsense? Generally speaking, we are a fair-minded and honest profession and we do our best for our patients. The national drug bill will best be reduced by an understanding of the best way in which to use drugs, but we shall never have time to keep up with recent advances if we are forced to spend our time finding ways, like owners of cheapjack stores, to undercut the costs of our colleagues."

The *British Medical Journal* comments that in view of the scathing remarks made from time to time by ministers of health and their political supporters on the large sums said to have been wasted on proprietary preparations, it comes as a surprise to learn that many of them cost less than the non-proprietary equivalent. Apart from the light it throws on the economical prices charged for most proprietary drugs, this booklet will not be of much interest to the great majority of physicians who are careful prescribers.

Medical Needs In Gold Coast.—Commenting on a report by Dr. Ian Fraser, the *British Medical Journal* says that the aim of medical administration in the British colonies has been that the quality of medical care should not be below British standards. In many colonies there are too few doctors to serve the population adequately, and in these the inhabitants cannot have their illnesses treated by qualified men. There is therefore a demand for unqualified practitioners. Dr. Fraser, who visited the Gold Coast last year at the request of the council of the B. M. A., describes the precarious position of the medical services in that colony, which now has a large measure of self-government and is being rapidly developed in other ways. Junior medical officers are required everywhere, and the shortage of specialists in a country that is building a 510-bed hospital is very serious.

Ultimately the Gold Coast's medical needs will be met by African doctors, and Dr. Fraser stresses the necessity for helping the African student and doctor to become well qualified. British medical schools can and do play an important part in training African doctors, but when the new hospitals are opened in the Gold Coast there is going to be a greater need than ever. Where are the specialists to come from? Uncertainty about the period of time which will elapse before the Gold Coast government may feel it can dispense with British doctors causes concern to the medical officers already in the colony and is bound to affect recruitment adversely, but the Gold Coast offers wonderful opportunities to medical men and women who are prepared to put up with disadvantages of life in the tropics and the problems of working for the government of a country subject to rapid economic and political change. Even so, most doctors contemplating service in the Gold Coast will want some assurance that they will not suddenly find themselves discarded. The B. M. A. is consulting the colonial office on this matter. Possibly an eventual solution will be found in the establishment of a Commonwealth Civil Service.

Causes of Visits to Doctors.—The common cold is the principal cause of a visit to or from the doctor, according to a report published by the registrar general. The report deals with the clinical records of eight family physicians during 12 months and says that one in eight of these doctors' patients was treated for a cold. Out of a total of nearly 28,000 patients, 1,485 males and 2,079 females were seen for this reason. Altogether 6,920 consultations were ascribed to the common cold, which, with bronchitis, influenza, and other respiratory diseases, accounted for a large proportion of the total consultations. Among the symptoms causing consultations were a cough, 1,230; headache, 566, mainly among women; and disturbance of sleep, 434. More than 3,000 consultations involved a diagnosis of psychoneurosis. Just over 1,000 were due to respiratory tuberculosis.

The physicians were consulted by about two-thirds of their patients during the year and gave an average of 3.8 consultations for each patient on their lists. Three out of five were by female patients, but, allowing for the preponderance of women on the lists, the excess is reduced to 25%. For male patients 70.7% of consultations were at the doctor's surgery and for female 66.3%. A total of 3,090 patients were referred to hospital outpatient departments, representing rates of 11.3 per 100 patients on the combined lists, 15.9 per 100 patients consulting, and 3 in every 100 consultations.

Encouragement of Private Practice.—At the Annual Representative Meeting of the British Medical Association this year a resolution was adopted deploring the absence of any constructive step toward the encouragement of private practice. The Private Practice Committee of the B. M. A. has been considering this problem. One member urged in the interests of the nation and of the profession that independent private practice should continue in healthy rivalry with the state service. Another considered that the survival of private practice would serve to keep an independent standard before the profession. Although it was suggested that the government was seeking to discourage private practice, it was recognized that official acceptance of a figure of 5% of the population as not participating in the service indicated that private practice was receiving at least passive encouragement. At present possibly the main difference between the two systems is in the way the patient obtains medical attention rather than in any great variation in the medical services provided. It was stressed that the continued existence of private practice depended as much on the economic situation as on public demand. The latter was unlikely to be very great unless marked changes occurred in the National Health Service. Unless such changes did occur it seemed probable that there would be very few private practitioners within a generation.

College of General Practitioners.—This newest British college is now one year old. Applications for foundation membership were invited on Jan. 1, 1953, and within three weeks 1,077 members and 142 associates were enrolled. By the end of six months the membership had almost doubled itself and there

were 130 overseas members. The founding council decided that the college ought not to be medicopolitical and that any political problems it might encounter should be referred to the appropriate committee of the *British Medical Association*. They also determined that the college should not interfere with the work of other medical organizations, but would interest itself in research, and in undergraduate and postgraduate education. In some matters, such as those concerned with group practice, the encouragement of closer ties between general practitioners and hospitals and the provision of adequate diagnostic facilities for all family doctors, the college will work in close association with the B. M. A. The Medical Research Council has set up a working party on which members of the college are serving to investigate the possibilities of clinical research by general practitioners. It has already been agreed that every foundation member of the college of less than 20 years' standing in practice, and without a higher degree, should accept 15 hours postgraduate instruction every year, or a week every two years.

Mentally Ill in Hospitals.—The Minister of Health has said that 43% of the hospital beds in England and Wales are occupied by persons suffering from mental ill-health. The proportion would probably be 50% if the patients included those in hospitals whose disease was as much of the mind as of the body. He said further that "the vast mental hospitals, some with more than 2,000 beds, are far away from our ordinary life and tend to be forgotten." The greatest problem is that of the aging population. We have ensured that people live longer, but we must do all we can to see that they are healthier and happier in the extra years given them.

Variations in Prescription of Drugs.—According to the Joint Pricing Committee for England, the area with the highest average cost per person for medicaments prescribed in 1952 was Chester. The cost there was \$4.35 per annum. The area with the lowest average cost was Huntingdonshire, where it was \$1.75. The area where most prescriptions per person were given was Wigan, with an average for the year of 8.17. At the other end of the scale was Huntingdonshire, with 3.28.

Doctors' Orchestra.—Dr. H. Ucko's appeal for music-loving members of the medical and dental professions in London to join him in forming an orchestra has been successful, and the orchestra had its first rehearsal recently. At present it consists of 21 violins, 3 violas, 10 cellos, 1 double bass, 2 flutes, 4 oboes, 6 clarinets, 1 bassoon, 2 horns, 1 trumpet, 1 trombone, and 1 tympani.

Research Clinic.—An Institute of Clinical Research and Experimental Medicine for the use of consultants of the Middlesex Hospital has been formally opened. It is the first in the country. Prof. A. Kekwick, director of the institute, said recently that already work is proceeding on cancer of the lung, the common cold, and the testing of drugs and anesthetics.

MEXICO

Wilms' Tumor.—According to studies made at the Children's Hospital, Mexico City, by Sariñana, Navarro, Salas, and Figueroa (to be published in *Boletín médico del hospital infantil*) of 54,375 patients who entered that institution between 1944 and 1951, 35 (0.06%) were found to have Wilms' tumor. Comparing the frequency of this tumor with that of all malignant tumors over a period of three years, it was found that one Wilms' tumor was encountered for eight malignant tumors of other types. Of the 35 cases studied, all presented an asymptomatic period of two to six months after discovery of the tumor and then more or less accentuated pallor, anorexia, and fever developed. The tumor was usually discovered by the mother of the patient and occasionally by routine medical examination.

Urinalysis revealed pus cells in 18 of the cases and red blood cells in only 3. In five the intravenous pyelograms were not diagnostic for Wilms' tumor. In three, after a retroperitoneal injection of air, it was impossible to see the kidney outline because adhesions prohibited the penetration of the air. The diagnosis was usually not difficult. Clinically, as well as radio-

logically, there were few doubtful cases. In one, neuroblastoma had to be ruled out. The elapsed time from the onset until hospitalization was five or six months. In five cases there was radiological evidence of pulmonary metastasis. All patients were treated surgically through the abdominal and transperitoneal route. In all cases the renal bed was irradiated the day after operation. Pulmonary metastases were treated in a similar manner. The operative mortality was 66%. Of the 12 patients who were alive at the time of writing, 5 had survived three and one-half years after operation; 3, two years; 3 more than one year; and one, less than one year. Most of the patients were less than 3 years of age, and one was 12 years old. The high mortality was due to the malignancy of the tumor and a failure to diagnose the condition early enough. Careful and systematic medical examination during the first three years of life will greatly aid in early diagnosis of this disease.

Damon Runyon Memorial Fund Grant.—This is the third year that the Damon Runyon Memorial Fund for Cancer Research, Inc., has given the Hospital de Enfermedades de la Nutrición in Mexico City a grant of \$5,000. This hospital and the cancer unit of the Hospital General in Mexico City have been working together under Dr. Francisco Gómez-Mont and Dr. Guillermo Montañón. Sixty patients have been treated with different steroids supplied by private laboratories. Doses of 500 mg. of progesterone were given intramuscularly every day to 20 patients until each patient had received 35 gm. Subjective symptoms improved and bleeding was reduced. Another 20 patients received 100 mg. of stilbesterol daily, with a total dosage of 8.485 gm. This also reduced bleeding. In the remaining 20 patients, who were given 500 mg. of testosterone propionate daily, bleeding was reduced, but tumoral necrosis increased. In none of the patients was there reduction in the size of the tumor or cytological or histopathological changes.

NETHERLANDS

Status of the Medical Profession in the Netherlands.—Sick funds have existed in the Netherlands for more than a century, and 50 years ago the Dutch Medical Association organized its own sick funds in which nearly 50% of all the insured in the country are enrolled. For the remuneration of the general practitioner, a capitation fee has been the usual system. Although the physicians have no objection to sick funds as such, the developments during and after World War II have led to a critical situation. Before the war all the sick funds were private institutions. The conditions under which the practitioners gave their services to the insured were based on contracts between the local professional groups and the local sick funds, without any intervention or supervision of government officials. These sick funds are responsible only for medical and pharmaceutical care in the broadest sense of the word.

The compensation of loss of wages by the employed, due to illness, is the subject of a sickness compensation act that is not administered by private organizations but by public or semi-public institutions. Such was the situation at the beginning of the war, but in 1941 the following drastic changes were brought about by the German occupation: 1. Sick fund insurance became compulsory for the employed and their families. 2. The maximum income for admission to the fund was no longer a matter of the local organizations, but became, at least for the compulsorily insured (70% of all the insured), fixed by the law in a uniform way for the whole country. 3. The sick funds lost their private character and came under state control. 4. The employers were obliged to pay half the premium of the compulsorily insured and thus became a potent factor in the control of the sick fund organizations. 5. The influence of the medical profession on these organizations was diminished in accordance with the growing influence of the new powers—the state and the employers. 6. The insured no longer formed a homogeneous group but were split up into voluntarily insured (30%) and compulsorily insured (70%) with different rights. 7. The total number of insured increased abruptly from 38% to 67% of the population as a whole. This growth was not so conspicuous in the urban districts (63% to 72%) as in the rural districts (16% to 49%).

In normal times there would have been opportunity for discussion by the medical profession and by the public, as well as in the Parliament, before such a law was accepted. During the war this was impossible, and, moreover, the physicians were too busy with the "medical resistance," which formed an outstanding part of the general resistance, to pay much attention to those important changes in their profession. They hoped and expected, however, that all those regulations, to which they strongly objected, would be reviewed after the liberation. The whole system, however, has been maintained, the only difference being that the "Führer-principle" was replaced by more democratic forms of organization. In the years after the war, the relations between the physicians and the sick funds became less cordial from year to year. One of the most difficult points was the determination of a maximum income that was compatible with membership in the sick funds. This limit was increased on several occasions, but the increases were based not on arguments of public medical care, but on economic, social, or political considerations. Because every increase of this limit diminishes the group of the persons forming the private practices, the medical profession in general did not concur in these measures. Furthermore petitions of the physicians for greater remuneration to compensate for the devaluation of the currency and increases in professional expenses were not acted on promptly. The specialists have not fared so badly, but the remuneration of the general practitioners is much too low.

At the end of 1953 after nearly a year of negotiations, an agreement between the general practitioners and the sick funds was reached that would result in a capitation fee of 7 florins each for the first 3,000 patients on a physician's panel and 5 florins for each additional patient; 3,000 patients is considered to be the optimum number for panel practice; a larger number is not encouraged. Approval for the new contract by the sick fund board was obtained with difficulty, and then the hope of its adoption was destroyed by the Minister of Social Affairs and Public Health. He judged the fee to be too high and postponed the execution of the regulations for three months. This intervention of the government is a challenge not only to the medical profession but also to the sick funds that hoped to save the small degree of autonomy left to them. The reaction of the medical profession was prompt. On Dec. 26 the general practitioners were summoned for a meeting. The meeting concluded that, because an agreement on a voluntary basis had been made impossible, the general practitioners will charge every insured patient a moderate private fee for a consultation. This new system of remuneration was to start Feb. 1, 1954.

PARIS

Experimental Tests on Tobacco Smoke.—In February, 1953, D. Vincent, G. Segonzac, and R. Lagrue reported the results of tests on tobacco smoke to the Society of Medicine, Surgery, and Pharmacy of Toulouse. The results of the inhalation of tobacco smoke on the bronchopulmonary tract in dogs who have been given chloral are the same as those observed following slow intravenous injection of small quantities of nicotine. Under the influence of a single cigarette, the blood pressure is suddenly doubled or tripled. The authors believe that this is due to adrenal stimulation. The blood pressure then gradually decreases. An initial polypnea is followed by a transient apnea. From 2 to 4 mg. of nicotine is absorbed during the smoking of one cigarette. The effects are less pronounced when denicotinized cigarettes are used. If a synthetic sympatholytic product is injected simultaneously, there is a fall in blood pressure instead of a rise. The authors believe that the sensation of release and tonic stimulation felt by smokers is due to adrenal stimulation, but this reaction, repeated in tobacco intoxication, might favor arterial atheroma and in diabetics an elevation of glycemia.

The Pathogenesis of Arteriosclerosis.—At a meeting of the French Society of Phlebology in June, 1953, A. Delaunay reviewed the theories of the pathogenesis of arteriosclerosis, namely, that it is due to (1) a disorder in lipid metabolism or (2) an exaggerated or abnormal hormonal activity. Among the hormones playing a role in this pathogenesis would be the de-

soxycorticosterone and desoxycorticosterone, epinephrine, thyroxine, and the pancreatic hormones. By injecting diethylstilbestrol into animals, vascular atheromas have been produced. Another theory, introduced by Moskowitz, is that the arterial lesions are caused by hypertension. Hueper believes that anoxia plays a leading role. R. Bourliere, who has long resided in the Far East, calls attention to the variable frequency of arteriosclerosis in people of different races and dietary habits. He found that in sedentary people with plenty of food arteriosclerosis was more prevalent than in rural populations with a limited food supply. On the other hand, Eskimos whose diet is very rich in fat rarely had atheromas. He therefore concluded that a diet rich in fats in hot or temperate countries and psychological stress predispose to arteriosclerosis. *Atheroma exists solely in the higher, warm-blooded vertebrates.*

Treatment of Lupus Erythematosus.—S. Sophroniadis has found an ingenious way to cure lupus erythematosus within a few days. He lets streptomycin penetrate into the affected tissues by iontophoresis. The skin is cleansed with double distilled water. An apparatus of at least 50 v. supplied with a milliamperemeter measuring intensities of 0.5 to 10 ma. and having lead electrodes is used. The active electrode is 2 to 8 cm. in diameter (being proportional to the lesion) and covered with pure cotton 1 cm. thick. This electrode is plunged into a fresh 0.05% solution of dihydrostreptomycin in double distilled water. The streptomycin solution leaves the positive pole. The ratio of the intensity of the current to the diameter of the active electrode must be 1:4. The number of treatments each of 5 minutes' duration is 6 to 10 for recent cases and 15 to 30 for chronic cases. During the treatment the author observed desquamation and hyperemia of the skin which disappeared a few days after the treatment was discontinued. This work was reported in the *Echos of Medicine* of Aug. 1, 1953.

New Products Inducing Hypocholesterolemia.—Cottet, Vignatou, Redel, and Calas-Belcours at a meeting of the Medical Society of Paris Hospitals in November, 1953, discussed a new drug that they call phenyl-ethyl-acetic acid. It is obtained by simplification of the molecule of biliary acids. Clinical studies were made on 135 patients to whom the drug has been given during a period of 2 to 12 weeks in daily doses of 2 to 3 gm. In 25 patients with a serum cholesterol of 251 to 410 mg. per 100 cc. there was a decrease in cholesterol following treatment in 23. In 51 patients with a serum cholesterol of 200 to 250 mg. per 100 cc. there was a decrease in 40. In 15 patients with a serum cholesterol of 150 to 199 mg. per 100 cc., there was a decrease in 8. The decrease in serum cholesterol appears to be in proportion to the initial elevation and to the duration of treatment. The initial level may be decreased 50% in seven or eight weeks. The drug is well tolerated and produces no albuminuria, erythema, or modification of azotemia. In 7 to 8% of the patients moderate gastralgia was observed.

Cardiac Auscultation.—A. Briskier has devised a method of graphically recording the heart sounds and simultaneously recording the sounds on tape. This enables the surgeon, during an operation, to appreciate the condition of the patient's heart and the obstetrician to follow fetal heart beats during birth. It also facilitates the teaching of cardiology. The microphone is so sensitive that the results registered are superior to those obtained by conventional auscultation. Certain heart murmurs that have not been distinguished by the stethoscope may be heard by this method. This has been reported in the *Archives of Heart and Vascular Diseases* of May, 1953.

Cardiac Protection in Surgery.—In June, 1953, J. M. Melon, J. Cahn, and Mlle. Dubrasquet reported a new technique of cardiac protection to the French Society of Analgesia and Anesthesia. This consists in the infiltration of the sinoauricular node with lidocaine (Lignocaine). This permits clamping for 17 minutes at a temperature of 84.2 F and prevents fibrillation of the heart. During the discussion, Huguenard stated that this method, interesting as it may be, does not protect the brain, but could allow, nevertheless, a profound artificial hibernation.

Doctor Roux's Centenary.—On Dec. 11, 1953, the centenary of Dr. Roux, the first disciple of Pasteur, was celebrated in the Sorbonne. Dr. Roux discovered diphtheria toxin and initiated treatment with antitoxin.

SPAIN

Congress of Leprology.—The Sixth International Congress of Leprology was recently held in Madrid under the chairmanship of Dr. J. A. Palanca and Dr. J. Gay Prieto and with the collaboration of Dr. M. Alvarez Cascos. The secretary of the congress was Dr. Contreras, the Director of the Leprologic Center of Trillo. The congress was organized by the International Association Against Leprosy. It met under the auspices of the government of Spain and the International Council on Organization of Medical Sciences, which corresponds to the World Health Organization. Its main function was to prepare regulations to be used throughout the world. Resolutions were drawn up by committees on classification, therapeutics, immunology, epidemiology, prevention, and social aid. All the resolutions were unanimously approved by the congress. Over 600 persons attended. According to the classification approved, leprosy may be lepromatous, tuberculoid, or indeterminate. Lepromatous leprosy is contagious, and *Mycobacterium leprae* is found abundantly in the lesions of this form. The resulting immunity is scanty, and the presence of Virchow's cells in the microscopic sections is typical of this form. The lesions of tuberculoid leprosy are granulomatous and contain few if any bacilli. As a rule it is only slightly contagious, if it is contagious at all. The immunity it produces, manifested by a positive Mitsuda's reaction, is good. The macular lesions seen early in the course of the disease are characteristic of the indeterminate form. This classification makes possible the recognition of those patients who need to be isolated and hospitalized. Patients with tuberculoid leprosy can continue to live in an active social environment without endangering the persons with whom they come in contact.

Sulfonamides are still the treatment of choice. Although treatment with these agents can result in total regression of leprosy and the cure of a large number of patients, the patients should be observed periodically for signs of recurrence. A continuation of the treatment after remission of the clinical symptoms reduces the incidence of recurrences. The value of thiosemicarbazone and streptomycin was pointed out. The Committee on Prevention recommended placing the responsibility of the crusade against leprosy on the dispensaries. The new drugs rapidly control the early lesions of leprosy and prevent the progression of early into advanced phases of the disease. This work as carried out in dispensaries should include periodic examinations of all normal persons who live in endemic zones in order to detect new cases early. The vaccination of normal persons who live in endemic zones with BCG increases resistance to leprosy. It causes the lepromin reaction to become positive. Vaccinated persons either do not acquire leprosy or, if they do, the disease is of the tuberculoid form. The use of BCG is free of any danger, even for persons who are sensitive to tuberculin. Some authors believe that a positive lepromin reaction in persons vaccinated with BCG is only the early development of a reaction that would have appeared later if the patient had not been vaccinated. The committee recommended standards for the organization of preventoria for children who had lived in endemic zones.

SWITZERLAND

Association of Cortisone and Phenylbutazone.—Because the beneficial effect of cortisone and corticotropin is limited to the duration of the treatment, many attempts have been made to prolong the effect by the concurrent use of other substances. Gsell and von Rechenberg (*Schweiz. med. Wchschr.* 83:1089-1092, 1953) studied the association of cortisone and phenylbutazone. In a preliminary period of two to four weeks, phenylbutazone was given parenterally to make the acute manifestations of chronic progressive polyarthritis disappear. The second therapeutic stage consisted in giving a total of about 1.5 gm. of cortisone in 12 to 20 days. In the third stage, phenylbutazone was again given. The results were satisfactory in 20 patients

treated in this way. The phenylbutazone tends to maintain the beneficial results obtained with cortisone and to prevent relapse. If these drugs are given concurrently on the other hand, the authors warn that there is danger of water retention, gastric ulcer, and granulocytopenia.

Staphylococcal Diarrhea Following Treatment with Antibiotics.—During a meeting of the Medical Society of Geneva in December, Bickel and Rentchnick reported a case of staphylococcal enterocolitis aggravated by chlortetracycline. The patient was a 15-year-old girl who, after having undergone a successful appendectomy, was given penicillin, streptomycin, and chlortetracycline in the first five postoperative days. Severe diarrhea soon caused an alarming dehydration, with sudden elevation of the body temperature up to 105 F. Stool cultures showed a strain of coagulase-positive *Micrococcus pyogenes* var. *aureus* (*Staphylococcus aureus*), which was resistant to penicillin. The patient was given erythromycin, and in 24 hours her temperature was normal, the diarrhea was checked. Four days later, there were no more staphylococci in the feces.

The 70th Birthday of Professor Frey.—The University of Berne celebrated the 70th birthday of Professor Frey, who is head of the medical clinic and has published two important books on the heart, the vessels, and renal diseases. In 1913 he introduced the test with epinephrine in the diagnosis of diseases of the spleen; in 1918 he introduced the use of quinidine in the treatment of auricular fibrillation; and in 1925 he described the sinking of the S-T segment of the electrocardiogram in patients with myocardial lesions. He is also the editor of the "Handbuch der Inneren Medizin."

The Vogt Prize.—The Swiss Society of Ophthalmology awarded the Vogt Prize to Professor Bamatter of Geneva, who in June, 1946, reported the first two cases of human toxoplasmosis. This disease, due to a protozoan transmitted to man by animals, causes typical ocular manifestations, which Bamatter reported in detail (*Ergebn. inn. Med. u. Kinderh.* 3:652-828, 1952). Of 74 patients known to have had toxoplasmosis, 50 had hydrocephalus, 10 paralysis, 39 cerebral calcifications, 5 strabismus, 9 nystagmus, 3 unilateral chorioretinitis, and 7 affections of the anterior segment of the eyeball.

New Hormone.—In a recent number of *Schweizerische medizinische Wochenschrift* (83:1088-1089, 1953), Reichstein and co-workers show that the new hormone electrocortine differs qualitatively and quantitatively from desoxycorticosterone. Quantitatively, it produces about 25 times as great a retention of sodium and about 5 times as great an increase of the elimination of potassium.

New Polyclinics of Geneva.—A sumptuous new five-story building for all the polyclinical services of Geneva has replaced the old. It includes a pharmacy, a transfusion center, a diagnostic laboratory, and otorhinolaryngology, surgery, medicine, and public assistance departments. The staff includes 20 physicians, 31 nurses, 11 social nurses, and 2 midwives.

Two International Congresses in Switzerland.—The International Congress of Gynecology and Obstetrics will be held from July 26 to 31 and the International Congress for the Study of the Bronchi will take place on June 5 and 6 in Geneva.

TURKEY

Pulmonary Abscesses and Penicillin Aerosol Therapy.—In *Anadolu Klinigi*, vol. 19, no. 4, Drs. Ihsan Aksan and Feyyaz Kasimoglu reported on 125 patients with pulmonary abscesses out of 21,416 admissions between 1943 and 1953. In recent years, there has been a marked decrease in the incidence of this condition. Of the 125 patients, 52 were treated with various drugs. Of these, 34 improved; 5 had no change; 5 died; and 7 were transferred to the surgical department. Of the 20 patients given emetine, 17 improved, one recovered, and 2 were advised to have an operation. Of the 12 patients given neoarsphenamine, 9 improved, and 3 had no improvement. Of five who were given acriflavine (Trypaflavin), three improved and in two an operation was indicated. The two given alcohol therapy improved.

Of the 34 patients given penicillin aerosol therapy, 17 were improved and 17 were cured. Experience with these 125 patients indicates that good results were obtained when the therapy of pulmonary abscesses was supplemented with antibiotics given parenterally or by inhalations and, when this failed, by tracheal insufflation. When thoracic puncture of the abscess, supplemented with antibiotic injections into the cavity, failed to have beneficial effects, an operation was recommended.

Tumor-Like Ascariasis.—Because of the primitive sanitation of rural Anatolia chronic ascariasis is common among the inhabitants. In *Dirim* (vol. 27, no. 8) Dr. Fatma Altug described a case of ascariasis in a 3-year-old boy that resembled an abdominal tumor. Until one year prior to admission he had been in good health; then pain and swelling in the abdomen developed. He became pale, listless, and irritated, and, although he had a good appetite, he did not gain weight. He had intense itching of the nose and profuse salivation at night, and once he passed an ascaris. Two months before admission a tumor-like, hard swelling developed in his abdomen. When this was massaged, it softened and the child felt relief. Because of diarrhea and vomiting the boy was brought to the hospital, where he was found to be emaciated and anemic. He had sunken eyes and a greatly distended abdomen. Parallel with the right rib edge, a smooth-edged movable tumor of moderate hardness measuring 5 by 10 cm. was palpable. The feces contained numerous ascaris ova. The patient was given a light supper, and on the next morning without breakfast he took a vermifuge and two hours later 25 cc. of castor oil. After three hours he passed 42 worms in a tight mass and on the next day 50 more, also in a tight mass. After this no trace of the tumor remained. The patient's health improved rapidly. Search for intestinal parasites is routine in outpatient clinics. Tight masses of ascarides are often encountered at autopsy in bodies of inhabitants of rural communities.

Ewing Tumor.—In *Dirim* (vol. 20, no. 10), Prof. Recai Ergüder and M. Naci Ayral described a case of Ewing's sarcoma, which is rare in Turkey. In the second surgical clinic of the Gülhane Military Medical Academy from 1942 to 1952, of the 22 patients who had sarcoma, only one had Ewing's sarcoma. According to world medical literature the percentage is 10 to 20. The patient was a 12-year-old boy. Pain in the left leg and knee began two months prior to admission to the hospital, and he had been treated for rheumatism without benefit. The pain and the swelling in the center of the left femur increased, and the patient rapidly lost weight. A biopsy specimen revealed a Ewing sarcoma. Amputation was advised but refused. The swelling rapidly increased, and the patient came to the Gülhane Hospital in Ankara. His left leg was edematous, and he had small, hard inguinal and axillary lymph nodes. Amputation was again refused. Radiotherapy was given by Prof. Mehmet Ali Taner, and within a month the tumor lost its hardness, the pain had decreased, and the axillary lymph nodes had disappeared. The patient's general condition improved for another month; then a hard painful swelling was noted in the testes; the liver and spleen descended below the costal margin; ascites developed; there was radiodermatitis above the femur; and the therapy was discontinued.

Five days later the patient complained of dyspnea and a cough. Sibilant and sonorous rales were heard in both lungs; there was pain under the left breast; and the patient died three days later of pulmonary edema and heart failure. Prof. Sureyya Taney of the Ankara Medical Faculty Institute of Pathology and Dr. Muzaffer Güldogan performed the autopsy. The tumor extended from the great trochanter to the condyle of the femur. It was gray, measured 14 by 18 by 38 cm., and weighed 4,500 gm. Sections revealed yellow necrotic areas chiefly at the periosteum. In the left lobe of the thyroid there was a tumor the size of a chestnut. Lymph nodes of the neck showed evidence of hemorrhage. There was a metastatic tumor at the hilum of the lungs. Hemorrhagic effusions were found in both pleural cavities. Tumors were also found under the left lobe of the liver, around the umbilical vein, the portal vein, the bile duct, and in the diaphragm, the omentum, and the cortex of the kidneys. The specimen of the tumor showed diffuse homogenous, polychromatic, hyperchromatic, pyknotic, atypical mitotic cell groups of various sizes.

CORRESPONDENCE

TRIBUTES TO THE PHYSICIAN

To the Editor:—The medical profession often comes under so much criticism that each physician is apt sometimes to become discouraged and to find his morale sinking to a low point. The recollection of some of the great tributes to the medical man may then be of real value in sustaining the sense of his own worth and restoring his satisfaction with his life work. For this reason, I have assembled here several of the most notable tributes to the physician for convenient reference.

So many physicians served in World War II and the Korean conflict that it is fitting that the first eulogy is to the military surgeon and comes from one of the most celebrated men of our generation, Sir Winston Churchill who recently received the Nobel Prize in literature. The quotation is from one of his earliest books "The River War." "The profession of medicine and surgery must always rank as the most noble that man can adopt. The spectacle of a doctor in action among soldiers, in equal danger and with equal courage, saving life where all others are taking it, allaying pain where all others are causing it, is one which must always seem glorious, whether to God or man. It is impossible to imagine any situation from which a human being might better leave this world, and embark on the hazards of the Unknown."

At a time when socialized medicine is being urged by many groups, this opinion of the English statesman William E. Gladstone is of interest. "Another point on which I congratulate the profession is its independence. It does not rely on endowment, but on its own exertions directed to meeting human wants. There is no great profession which has so little to say to the public purse, and which so moderately and modestly dips its hand into that purse. It is not only in the interest of the public, but of the profession itself, that is eminently self-supporting; and, rely upon it, that the principle of self-support does much to maintain its honour and independence, and to enable it to pursue its stately march in the times that have come and in the times that are coming, to form its own convictions, to act upon its own principles without fear or favour, for the general benefit of mankind." This is from an address delivered at Guy's Hospital, London, in 1890. As a declaration against state medicine, it is just as appropriate in 1954 as it was 64 years ago.

Two great novelists have eulogized the physician. The best known tribute is that of Robert Louis Stevenson. "There are men and classes of men who stand above the common herd, the soldier, the sailor, the shepherd not infrequently; the artist rarely; the physician almost as a rule. He is the flower of our civilization and, when this stage of man is done and only to be marveled at in history, he will be thought to have shared as little as any in the defects of the period and most nobly exhibited the virtues of the race. Generosity he has, such as is possible to those that practice an art, never to those who drive a trade. Discretion, tested by a hundred secrets, tact tried in a thousand embarrassments, and what is more important, Herculean cheerfulness and courage." Dickens, in "Bleak House," expressed his golden opinion of the medical man through the words of the heroine of that novel. "I never walk out with my husband, but I hear the people bless him. I never go into a house of any degree, but I hear his praises, or see them in grateful eyes. I never lie down at night, but I know that in the course of that day he has alleviated pain, and soothed some fellow creature in the time of need. I know that from the beds of those who were past recovery, thanks have often, often gone up, in the last hour, for his patient ministrations. Is not this to be rich? The people even praise *Me* as the doctor's wife."

Virtually no phase of life goes unnoticed in the Bible, and sickness and the physician are not forgotten. The author of Ecclesiastes expresses the dependence of society on medicine: "Then give place to the physician, for the Lord hath created him: let him not go from thee, for thou hast need of him." The prophet Jeremiah also tells of this need with the question "Is

there no balm in Gilead? Is there no physician there?" Homer declared that "The physician is worth many other men" and that "The wise physician skilled our wounds to heal is more than armies to the public weal." This is another reference to the value of military medicine, apparent even in Homeric times.

In Ian MacLaren's "A Doctor of the Old School" a book length tribute is paid to the country physician. This work, written more than 50 years ago, has become a classic and would make an excellent moving picture. In these days of communism, anti-imperialism, and numerous other isms, Kipling has gone out of style. He was and is, however, one of the giants of literature. Nearly 50 years ago in speaking to a group of medical students he said words of praise of the physician's calling that deserve to be recalled to mind. "It seems to be required of you that you must save others. It is nowhere laid down that you need save yourselves. That is to say you belong to the privileged classes. May I remind you of some of your privileges? You and kings are about the only people whose explanation the police will accept if you exceed the legal limit in your car. On presentation of your visiting card you can pass through the most turbulent crowd unmolested; even with applause. If you fly a yellow flag over a centre of population you can turn it into a desert. If you choose to fly a Red Cross flag over a desert you can turn it into a centre of population toward which, as I have seen, men will crawl on hands and knees. You can forbid any ship to enter any port in the world. If you think it necessary to the success of any operation in which you are interested, you can stop a 20,000 ton liner with her mails in mid-ocean till that operation is completed. . . . At a time when few things are called by their right names, when it is against the spirit of the times even to hint that an act may entail consequences, you are going to join a profession in which you will be paid for telling men the truth, and every departure you may make from the truth you will make as a concession to man's bodily weakness, and not his mental weakness."

Perhaps the finest tribute to the medical profession is the ethical concept contained in the Hippocratic writings. This may be summed up in a single sentence: "That which is for the greatest benefit to the patient is the first consideration of the physician." This should be printed in letters of gold and placed on the wall of every physician's waiting room and office. This motto and its observance by our profession would promote the best relations between physician, patient, and public.

San Diego, Calif.

BOOKS FOR CHRISTIAN MEDICAL COLLEGE

To the Editor:—A short time ago I visited the Christian Medical College at Ludihana, Punjab, India, under the direction of Dr. Fred Scovell. In talking to Dr. Scovell, I discovered that this medical college is in great need of current medical books and pamphlets to carry on effectively its training of students in that area. Current books and pamphlets are not too available at this college in view of the fact that it is on a limited financial program and in a remote area of the world.

I know that many physicians would be glad to share their books with an institution of this kind. They could send the books to Dr. Fred Scovell, Christian Medical College, Ludihana, Punjab, India. If the physicians do not care to undertake the expense of transportation of the books, I would be glad to have them send them to me and I will in turn see that they are forwarded to the college.

OTITIS EXTERNA

To the Editor:—I was interested in the article entitled "Otitis Externa: The Facts of the Matter" by J. W. McLaurin (*J. A. M. A.* 154:207 [Jan. 16] 1954). I have never seen primary mycotic eczematous otitis externa or primary bacterial eczematous otitis externa. In my experience, eczematous otitis externa has been caused by (1) psoriasis vulgaris, (2) otitis media with perforation and otorrhea, (3) seborrheic dermatitis, (4) atopic dermatitis, (5) neurodermatitis, (6) contact dermatitis, (7) dermatitis medicamentosa from drugs injected, ingested, or applied topically, or (8) a combination of two or more of these. Obviously, bacterial infection may be superimposed on all of these conditions. Of all the causes of chronic eczematous otitis externa that I have listed, I have found that psoriasis vulgaris is not only the one most frequently met, but the one least often diagnosed. As psoriasis affecting other cutaneous parts of the body, eczematous psoriatic otitis externa is chronic and unpredictable in its course and response to treatment.

Since the otolaryngologists, general practitioners, and internists usually see and treat external otitis initially, I advise them to examine the patient's skin and nails for evidence of psoriasis elsewhere and to question him about the presence of psoriasis in other members of the family. Unhappily, eczematous external otitis may be the first and only manifestation of psoriasis and may be present for months and years before psoriasis appears on other parts of the body.

C. RUSSELL ANDERSON, M.D.
416 N. Bedford Dr., Beverly Hills, Calif.

To the Editor:—In the Jan. 16 issue of *THE JOURNAL*, Dr. McLaurin has written a fine article about the principles of treatment of otitis externa. From the dermatologist's point of view, however, he has omitted one of the principles that we consider most important. That is that the commonest cause of otitis externa is seborrhea, and, unless one looks for it in the scalp and treats that area too, one will make little progress in treating the ear. Diffuse scaling of the scalp, with or without inflammation, is an indication for treatment of the scalp as well as the ear with any of the standard preparations for this cause. Treatment of the ear with neglect of the scalp is almost certain to give a poor or only temporary response.

NORMAN M. O'FARRELL, M.D.
340 Kalmia St., San Diego 1, Calif.

THE PARIETAL LOBE

To the Editor:—Regarding the monograph "The Parietal Lobe" by Macdonald Critchley (reviewed in *THE JOURNAL*, Jan. 9, 1954), it should be pointed out that approval or disapproval of the work will depend on the point of view, of which there are at least two. Although Critchley strongly supports the thesis that each symptom described represents a loss of some mental element, there are others who believe that the various symptoms are functional in nature and that they indicate, at most, a general emotional instability. Bay (*Brain* 76:515-550 [Dec.] 1953) after a long and elaborate study concludes that the conception of "agnosia" is invalid; and it should be added that agnosia includes most of the symptoms described in Critchley's monograph. Weinstein and Kahn (*A. M. A. Arch. Neurol. & Psychiat.* 69:355-367 [March] 1953) find that personality factors determine the "denial of illness" in hemiplegia. As the author mentions, Jung examined one celebrated, much-studied patient with agnosia and stated that a psychiatrist would reach no such conclusions as the others had done. My own article (*J. Nerv. & Ment. Dis.* 91:190-209 [Feb.] 1940) encompassed the whole range of symptoms associated with this general area of the cortex, and I stated that they were best understood as basically functional manifestations.

It is true that this part of the brain produces, either spontaneously or on examination (perhaps by suggestion), a curious lot of symptoms and so at least is associated with an unusual degree of instability. It is impossible in one short letter to go into all the arguments, as I tried to do in my monograph "Cerebral Localization: Outline of a Revision." But, as Critchley admits,

there occur "negative cases," that is to say, cases in which similar lesions fail to yield anticipated signs. The occurrence of negative and positive findings, respectively, could mean that the real influence is exerted on centers at a distance from the lesion, through the medium of surrounding tissue and vascular reactions, which can be demonstrated to occur. These reactions may sometimes extend as far as the underlying thalamus, the supposed seat of certain emotional disturbances. Hence, there is the experience of contradictory negative and positive findings and of special instability associated with this part of the cortex. It appears that from one point of view, the pictures described and the inferences drawn in the monograph cited are questionable.

EVALUATION OF TOXICITY OF CHEMICALS

To the Editor:—I refer to the article "Perspective Versus Caprice in Evaluating Toxicity of Chemicals in Man" by Dr. M. H. Seevers in the Dec. 12, 1953, issue of *THE JOURNAL*. It makes a highly valuable contribution in the clear and logical statement of five principles on which the evaluation of toxicity in human beings must be based. This is a splendid guide in considering the use of chemicals in foods. Dr. Seevers' distinguished work in pharmacology has been known for many years. It is regrettable that the over-all value of the article is impaired by a number of erroneous assertions and implications in the discussion preceding the statement of principles. Most glaring of these is the assertion that, "For approximately 50 years, the food division of the Food and Drug Administration has adhered to a basic administrative policy that no chemical shall be added to foods." There is no such administrative policy; there never has been. This is clear from even a casual reading of the food standards, which recognize the use of many chemicals, and other relevant pronouncements under both the laws of 1906 and 1938.

As evidence that the Food and Drug Administration has adhered to this alleged policy, Dr. Seevers offers the following quotation from an extemporaneous statement by former Commissioner P. B. Dunbar before the House Select Committee to Investigate the Use of Chemicals in Foods: "I feel that no chemical or no new chemical that is subject to any question as to safety should be employed until its possible injurious effect, both on acute and over a long-time chronic basis, has been shown to be nonexistent. In other words, any chemical that is proposed for use ought to be approved in advance of distribution in the food product to be utterly and completely without the possibility of human injury." Page 36 of the published report of hearings before the committee shows that Dr. Dunbar used the word "proved" where Dr. Seevers uses "approved" in the last sentence of the quotation. Dr. Seevers omitted the highly significant sentence that immediately follows and that reveals the meaning Dr. Dunbar was trying to convey: "What I think we need is an amendment which we might call the new chemical section, which will make the proponent of a new chemical, the addition of a new chemical, present the same type of convincing proof of safety that is now required in the case of new drugs before interstate commerce is undertaken."

Elsewhere in his article Dr. Seevers said: "American physicians are indeed fortunate in being able to inform their patients that drugs purchased on prescription or for self-medication are almost certain to be of proper identity, purity, quality, and quantity. This situation is virtually guaranteed by the wise provisions of the Food, Drug, and Cosmetic Act of 1938, especially the new drug section, which requires approval in advance of distribution. In the main, fair perspective has been maintained in administering the act as it relates to drugs. . . ." It seems, therefore, that Dr. Seevers approves the very procedure that Dr. Dunbar was advocating before the House Select Committee. As you know, the new drug section requires testing only by "methods reasonably applicable to show whether or not such drug is safe for use. . . ." That perfection is not contemplated by the law is further evident from the provision that a new drug admitted to the market on the basis

of such tests may subsequently be banned when "clinical experience, tests by new methods, or tests by methods not deemed reasonably applicable . . . (when the drug was admitted to the market) show that such drug is unsafe. . . ." The applicability of these provisions to new chemicals in food, within the framework of the five principles Dr. Seevers has set forth, is clearly apparent. Had methods employed by science in its search for truth been followed by Dr. Seevers, he would have found many published expressions by Dr. Dunbar and members of his staff that show adherence to the philosophy of the new drug section even before it was enacted in 1938.

After having postulated a nonexistent and indefensible policy for the Food and Drug Administration, Dr. Seevers accuses the organization of "a studied attempt to confuse and mislead the public," of establishing "standards that are impossible to attain regardless of conditions of use," and of using "incompetent witnesses or pseudoscientists to bolster up administrative decisions and influence legislation." He cites as an example of this type of action the decision banning the use of bread softeners, which he says "cannot be considered to represent a biological hazard under present conditions of use." Dr. Seevers' view on this point is not shared by the Food Protection Committee of the National Research Council. This committee, which is composed of distinguished scientists, studied the entire record in this case and rendered a report supporting the government's action. We in the Food and Drug Administration must leave the settlement of such issues to the consensus of the nation's scientific experts who are qualified by training and experience in the particular field involved in each case. Dr. Seevers' assertions that the decision on bread softeners was to influence legislation and that the decision on the use of nitrogen trichloride in flour "was designed primarily, if not exclusively, to influence legislation" are utterly without foundation, as are many of his other statements and implications on which I will not comment specifically at this time.

In his article Dr. Seevers invades the field of law enforcement, public administration, and legislation. In going outside his own scientific specialty, it is unfortunate that he did not carry the faculties of thoroughness and objectivity in search for truth that have characterized the contributions he has made in his own field. These erroneous representations do not lend perspective to consideration of the important health problem involved in the growing use in food of chemicals that have not been adequately tested to evaluate their hazard and do not contribute to solution of those problems.

C. W. CRAWFORD
Commissioner of Food and Drugs
Food and Drug Administration
Washington 25, D. C.

To the Editor:—An article by Dr. Maurice H. Seevers in *THE JOURNAL*, Dec. 12, 1953, bears the title "Perspective Versus Caprice in Evaluating Toxicity of Chemicals in Man." It is concerned largely with some questions relating to the toxicity of chemical additives to foods. It is unfortunate that in the development of his theme, which seems to be the formulation of certain so-called basic principles for the evaluation of the toxicity of chemicals, Dr. Seevers has presented an inadequate and misleading picture of the work of the Food and Drug Administration to protect the public health under the existing laws that that agency administers and of the work of the Delaney Committee of the 81st and the 82nd Congress to investigate the need for additional legislation relating to food additives.

It is not my purpose to do more than mention a few of the facts that should indicate that a sincere and considered effort has been and is being made to incorporate a new food additive section in the federal Food, Drug and Cosmetic Act. At the present time, regulatory control over the safety of new chemicals, or of old chemicals put to new uses, applies only to drugs and not to foods or cosmetics. The need for revision of the federal laws to correct these deficiencies has been pointed out repeatedly by persons who can hardly be characterized as crackpots, self-styled scientists, or even well-meaning but misinformed reformers. In 1949 the Committee on Chemicals

Introduced in Foods, of the American Public Health Association's food and nutrition section, was established. This committee now consists of the following persons, each of whom has served on the committee since its creation: William J. Darby Jr., M.D.; Smith Freeman, M.D.; Robert W. Pilcher, Ph.D.; Bernard E. Proctor, Ph.D.; Harold R. Sandstead, M.D.; Henry T. Scott, Ph.D.; and Franklin C. Bing, Ph.D., chairman. Several reports of this committee have been published. In its very first report, this committee called attention to the growing use of chemicals in food production and processing and to the need for orderly, scientific consideration of such uses. The committee recommended the enactment of legislation to require approval, prior to use, of newly proposed additives to foods. This recommendation, in the form of a resolution, was adopted by the governing council of the American Public Health Association in 1949.

The Delaney Committee of the 81st Congress was created in 1950 for the purpose of investigating the use of chemicals in food products. Its membership consisted of congressmen Thomas G. Abernethy, E. H. Hedrick, M.D., Paul C. Jones, Frank B. Keefe, A. L. Miller, M.D., Gordon L. McDonough, and James J. Delaney, chairman. The scope of the committee's work was expanded by the 82nd Congress to include an investigation of chemicals in cosmetics as well as in foods. Its membership remained the same, except for the appointment of Congressman Walt Horan in place of the late Congressman Frank B. Keefe. The chief counsel for the committee was Vincent A. Kleinfeld. It was my privilege to serve as consultant and member of the staff of the Delaney Committee throughout most of the period of its existence. This committee conducted hearings in Washington, D. C., Chicago, Spokane and Seattle, Wash., San Francisco, Los Angeles, and New York. Members of the committee visited laboratories of food processing companies and in other ways made a serious effort to ascertain what the problems were and what industry was doing to control them. There were over 200 witnesses who appeared before the committee, who presented statements under oath, and who were questioned by counsel and by members of the committee. Statements were submitted by a few persons who did not appear in person. There were, in addition, many letters, documents, and other pertinent items that were studied. The records of the hearings alone cover several thousand printed pages.

The Delaney Committee's reports and recommendations were based on a study and an evaluation of all of the available evidence. The qualifications of the persons who presented testimony were, of course, taken into consideration in evaluating the weight of the evidence that they introduced. In brief, these reports to Congress recommended, among other things, that legislation be enacted that would require the presentation of proof of safety under the condition of use of additives to cosmetics and to foods before these additives would be permitted to be put in articles in interstate commerce. All of the committee members signed the report on cosmetics; five of the seven members signed the report on food additives. Before and since the presentation of its final reports to the 82nd Congress in 1952, executives of food and chemical companies likely to be affected by the kind of legislation recommended in the majority report on foods of the Delaney Committee have gone on record as being in favor of the enactment of suitable legislation. Several associations of important food processing industries have adopted statements in support of the control of chemical additives to foods by suitable amendments of the federal Food, Drug and Cosmetic Act.

There are many persons who disagree with the suggestion of Dr. Seevers that a committee outside the Food and Drug Administration be appointed to assure the public of "valid technical as well as moral justification" for any decisions that might be made. In my opinion, authority to administer the broadened law, which is being given consideration, can well be assigned to the Food and Drug Administration without any reviewing body except the courts, but with sufficient financial provision to permit adequate enforcement in the public interest.

MEDICAL MOTION PICTURES

MOTION PICTURE REVIEW

The Management and Mismanagement of Breech Presentation: 16 mm., color, sound, showing time 18 minutes. Prepared by A. C. Mietus, M.D., Department of Obstetrics and Gynecology, University of California School of Medicine. Produced in 1953 by Riviera Productions for Boyle and Company Pharmaceuticals, Los Angeles. Procurable on loan or purchase from A. C. Mietus, M.D., 1245 Glendon Ave., Los Angeles 24.

This film opens with remarks emphasizing the hazards inherent in breech presentation. The technique of prophylactic external version is demonstrated and decomposition of the breech is discussed. An assisted breech delivery is executed on a manikin, emphasizing the fundamentals and niceties of technique. The use of forceps on the aftercoming head is illustrated. Then, on the manikin, the mismanagement of a breech delivery is shown. Here the commoner errors in technique are shown. Finally, an actual breech delivery of a human subject, reemphasizing correct methods, is shown. The film closes with a brief discussion of the indications for cesarean section and a plea for obstetric conservatism. It is to be regretted that the subject of anesthesia is not more completely discussed. The necessity of assistance in breech delivery goes unmentioned. Slight pressure over the symphysis is also disregarded in the delivery of the aftercoming head. As it now stands, the film is incomplete; however, it will be of interest to general practitioners, residents, interns, and medical students.

Congenital Anomalies of the Ear, Genesis and Correction: 16 mm., color, silent, showing time 37 minutes. Prepared by George E. Shambaugh, Jr., M.D., and Eugene L. Derlacki, M.D. Produced in 1953 by Mervin W. La Rue, Inc., Chicago. Procurable on loan from Medical Audio Visual Education Department, Northwestern University, 303 E. Chicago Ave., Chicago 11, or on purchase from George E. Shambaugh, Jr., M.D., 55 E. Washington St., Chicago 2.

The stated purpose of this film is to present the authors' views on why more than one surgical technique must be considered in the correction of congenital anomalies of the external and middle ear. The findings vary in each case according to the stage of arrest in the embryological development of the external and middle ear. The embryological development of the external auditory canal, eustachian tube, the middle ear, and the conduction apparatus is illustrated by a series of drawings in color. Several clinical cases are then described that present different types of congenital defects and malformations of the external ear and conduction apparatus. These defects are then related to the period in the growth of the embryo at which the arrest or deviation from the normal took place. A detailed description of the embryology is not attempted and would scarcely be practical in a film of this length. The film is to be considered as a review of certain essential features of the embryology rather than as a detailed account. It therefore has greater value to the aural surgeon in relating the congenital defect to a certain stage in the development of the embryo than to the student in embryology. To the surgeon, the film demonstrates the method used by the authors for dealing with certain defects of the conduction apparatus and the external auditory meatus and results that they have obtained. The photography is excellent. The film should be of definite value to the otologist and the aural surgeon.

Viral Hepatitis: (FG 8-6): 16 mm., black and white, sound, showing time 20 minutes. Produced in 1953 by the Department of the Army. Procurable on loan from the surgeon of the army area in which the request originates.

This motion picture attempts to demonstrate, mainly by animated drawings, the basic facts of viral hepatitis. After a short reference to the military significance of this disease, the epidemiology, clinical symptomatology, physical and laboratory findings, treatment, and pathology are discussed. The differential diagnosis of hepatitis with and without jaundice is schematically presented. Here the picture is somewhat oversimplified, and not everyone will agree with some of the statements made. The prognosis is discussed with valuable emphasis upon the danger of chronic hepatitis, which is said to be avoidable with proper treatment, bed rest being most important.

The statement that 1% of patients die during the acute stage and 2% suffer from chronic hepatitis one year after the onset of the disease is surely correct for patients in the armed forces but may not necessarily apply to civilians. The animation is clear and simple, and the motion picture is very well organized. It can be recommended for presentation to hospital staffs, especially to stress the importance of chronic hepatitis.

BUSINESS PRACTICE

The following material is based on a public relations manual issued by the Public Relations Department of the American Medical Association.—Ed.

MEDICAL ASSISTANTS

If a doctor employs a combination nurse, secretary, and receptionist who presides over the waiting room, assists with patients, and does the clerical work, she is a key person in determining what patients think of a physician and his office. The good will of the patients is in her hands. Some physicians succeed with the help of good assistants, and others succeed in spite of their office personnel. Thoughtlessness or carelessness on the part of an assistant can spell doom for a doctor's public relations. A neat, attractive assistant is "good medicine" for any patient. As the physician's good-will ambassador she should have a pleasing personality that combines friendliness, courtesy, graciousness, and sympathy. A girl who dislikes people or becomes impatient with them should not work in a doctor's office. A sad-faced girl, one who is bored or wears a perpetual sneer, or a dragon who strikes terror into the hearts of patients is no asset to a physician. His assistant should be cheerful, tactful, and efficient, prepared to meet any emergency with cool-headed composure. In order to find such a paragon, one physician suggests using the systematic techniques developed by personnel experts—job evaluation, careful screening, and testing of applicants—rather than the hit-or-miss approach. Although ready-made kits that provide interview guides and necessary forms are available from the Personnel Institute¹ or the Psychological Corporation,² similar materials can be designed to fit individual needs.

Before considering any applicants for a job as assistant, a physician should decide exactly what tasks the job entails and what qualifications in terms of age, marital status, and education the applicant should have. He may then enlist the aid of his colleagues or friends, schools training the type of assistant he wants, and employment agencies. He may also advertise in newspapers or professional journals for applicants. In interviewing an applicant he should particularly notice her voice, poise, intelligence, education, and ambition. He should have applicants fill out a personal history form and hold a final interview with the best applicants. He should get an opinion, by phone if possible, from a past employer.

An efficient assistant can save time and money for a physician, but she must be thoroughly trained. Her duties should be clearly and specifically outlined, and she should not be expected to learn everything the first day. The importance of attention to detail should be impressed on her, and she should be warned that mistakes in a doctor's office can be tragic. The importance of maintaining patients' office confidences should also be stressed, and an agreement on just what procedures are to be followed in specific situations should be worked out in advance. Many a doctor's assistant is reduced to tears when her employer flails her verbally in front of a patient for a slip-up. This should never be done. She should be encouraged to tell her grievances to her employer and to make suggestions. Good assistants deserve good wages. It is foolish to hire a girl merely because she will work for a pittance. Most girls do not mind working overtime occasionally, but this should be rewarded with a little time off now and then or with a substantial bonus. A loyal, personable, and well-trained assistant can be a doctor's greatest public relations asset.

BUREAU OF LEGAL MEDICINE AND LEGISLATION

MEDICOLEGAL ABSTRACTS

Governmental Hospitals: Right of Staff Member to Practice Surgery.—This was a suit for an injunction to restrain the director and members of the senior attending staff of the Irvington General Hospital from denying the plaintiff the right to perform major surgery on his patients in the hospital. The suit was heard in the superior court, chancery division, New Jersey.

The plaintiff graduated from George Washington Medical School, with honors, in 1935, served his internship in recognized hospitals, and pursued postgraduate courses in surgical technique. In 1936, on receiving his license to practice medicine and surgery in New Jersey, he commenced to practice in Irvington. From January, 1941, until August, 1945, he was in the U. S. Army serving as attending surgeon at Fort Bragg, N. C., and later as battalion surgeon in the European theater of operations. On his honorable discharge, he resumed practice in Irvington. The Irvington General Hospital is the only hospital in Irvington and is a public institution operated and maintained by the town. It is used by the residents of Irvington, including the patients of the plaintiff. The plaintiff testified that in 1945 he was a member of the surgical staff and performed major operations upon his patients and assisted other doctors in similar operations. By a letter dated March 3, 1950, signed by the secretary of the hospital staff, the plaintiff was notified that at a recent meeting the staff decided, "That you will operate with a member of the Surgical Committee assigned, and that this Committee will endeavor to equalize the number of cases which each member will supervise." Under the date of March 20, 1950, he was informed by letter "that at the last regular meeting of the Medical Staff of the Irvington General Hospital, the Staff has decided that you are to have no privileges to do major surgery." The meetings of the staff preceding these communications were held without notice to or attendance by the plaintiff. He had not been notified or apprised of any charges against him, and, in fact, none have been made or filed against him. His loss of the right or privilege to perform major surgery on his patients was without cause so far as any formal record was concerned.

From 1934 to 1950, the management of the defendant hospital was under the direction of Percy A. Miller Jr., the Director of Public Affairs of the municipality, and since May, 1950, it has been under the direction of his successor on the town commission, the defendant, John R. Martin. Neither the board of commissioners nor the directors of public affairs, although permitted to do so, prepared or formulated any written rules and regulations pertaining to the hospital. Director Miller testified that it was his policy as administrator of the hospital to conform to the standards of the American Hospital Association and other similar organizations; that while they were not published or reprinted by him, he used them as guides in his administration. However, no formal rules and regulations were available to interested persons, although their adoption was required by the ordinances providing for the creation and maintenance of the hospital. Both Miller and Martin are laymen, and in the administration of the hospital they relied on the recommendations of the medical staff, which had adopted a constitution and rules and regulations. These rules and regulations set forth the various divisions of the medical staff but contain no provision requiring any special qualifications, training, or experience for physicians performing surgery at the hospital. The rules and regulations also provide that any member who, on investigation, has been found guilty of unprofessional or unethical conduct or violation of the constitution and by-laws of the staff may be rec-

ommended for suspension or expulsion for such conduct or violation. The rules then set forth the procedure to be followed in the case of such expulsion or suspension.

Whatever may be the legal effect of the constitution and the rules and regulations of the medical staff on the rights and privileges of the plaintiff, said the court, even if we were, merely for the purposes of this proceeding, to accord them binding effect, it is nevertheless true that no charges were ever preferred against the plaintiff. The defendants, members of the medical staff, testified that there was no specific complaint made against the plaintiff. If there was any basis for the suspension or revocation of the plaintiff's privileges, the procedure stipulated by the rules and regulations of the staff should have been followed, and in conformity with this procedure the plaintiff should have had an opportunity to appear and defend himself. The absence of compliance with their own rules and regulations, concluded the court, renders invalid the disciplinary action of the medical staff.

The plaintiff contended that he has the right to use the facilities of the hospital for surgery "under the same terms and conditions as those afforded to any other person licensed to practice medicine and surgery at said institution." The defendant, Director Martin, contended that he will not permit the plaintiff to perform major surgery because "it is his studied opinion . . . that the plaintiff lacks sufficient training and experience in the field of major surgery," that the staff serves "at his pleasure," and that he may "at his pleasure" remove physicians from the staff.

The general rules pertaining to the issue raised by this case are clear and well settled. A municipality may, of course, establish a public hospital. A hospital may prescribe reasonable rules concerning the qualifications of physicians allowed to practice therein. While the issuance of a license to practice medicine and surgery by the State Board of Examiners evidences the qualifications and the rights of the holder thereof to practice within the state, it does not give him the right *per se* to practice in a municipal institution. Obviously, the court continued, a municipality in the exercise of its duty to prescribe reasonable rules and regulations should set up standards or qualifications for those who wish to serve in the hospital; these should be general and not arbitrary or discriminatory; they should be clear and not vague, ambiguous, or uncertain. Thus, it would be perfectly reasonable for a municipality or those charged with the administration of the hospital to require that in order to perform major surgery, the physician be a diplomate in surgery, a fellow of the American College of Surgeons, or that he serve a probationary period. Such rules and regulations, being general and equally applicable to all licensed doctors, would be merely a means of defining and clarifying in the public interest the standards of the institution. However, in the instant case, said the court, the town and its directors did not formulate any set of rules and regulations. The defendant, director of public affairs, claims the right to act "at his pleasure." Such conduct is arbitrary and contrary to public policy or good administration. The rules and regulations of the medical staff have no binding effect, except as the plaintiff voluntarily agreed to be bound thereby. But it is obvious from the testimony that the medical staff not only failed to set up satisfactory standards or qualifications but also failed to observe those regulations that they did adopt pertaining to the filing of charges against staff members and the holding of hearings thereon before recommending to the director so serious a consequence as the deprivation of the plaintiff's privileges. It is clearly shown from the testimony, the court continued, that the plaintiff's privilege of performing major surgery on his patients, residents of the Town of Irvington who may be lawfully admitted to the hospital, has been and is being arbitrarily denied him. He is being deprived of the privilege without justifiable cause being stated. Accordingly the injunction requested by the plaintiff was granted and the hospital was restrained from denying the plaintiff the right to practice major surgery on his patients in the hospital. *Jacobs v. Martin*, 90 A. (2d) 151 (New Jersey, 1952).

Phrenic or Postemphysematous Hypertension.—Geschickter and Popovici call attention to the probable role of emphysema or pulmonary rigidity as a factor in essential hypertension. To emphasize that they are not referring to hypertension of the pulmonary circulation, they labeled this form postemphysematous or phrenic hypertension. Sixty of 75 patients over 40 years of age with a history of asthmatic attacks of two or more years' duration had emphysema, and 28, or 46% of them, had arterial hypertension. Using similar standards for the upper limits of normal blood pressure (160/90 mm. Hg), the corresponding percentage of persons with hypertension in the general population is between 20 and 25%. In 15 patients with extrinsic emphysema not complicated by asthma but resulting from factors such as fixation of the chest wall from spondylitis, senility, and osteoarthritis hypertension also occurred, particularly in cases complicated by pulmonary fibrosis or by lordosis in association with abdominal obesity. It is concluded that long-standing emphysema with loss of negative intrathoracic pressure in patients over 40 can lead to hypertension, particularly when the emphysema is complicated by bronchial asthma or pulmonary fibrosis or when it concurs with postural lordosis and obesity. Phrenic hypertension seems to result from loss of intrapleural negative pressure, with increased venous pressure associated with renal congestion and compensatory arteriolar spasm. The role of venous congestion in hypertension can be demonstrated by placing the patient with emphysema in recumbent lordosis, which compresses the inferior vena cava. In normal persons the blood pressure is either lowered or remains constant. In persons with hypertension the systolic pressure is slightly elevated and the diastolic pressure is elevated from 15 to 20 mm. Hg or more. The blood pressure in patients with phrenic hypertension is even more elevated if the patients stand upright in a position of lumbar lordosis. Bad posture

with abdominal obesity added to emphysema seems to be one of the factors leading to hypertension in overweight persons with moderate emphysema. When pressure in the inferior vena cava is increased by tilting the patient downward or by his standing in the lordotic position, renal plasma flow is reduced and diastolic pressure elevated. In two dogs rendered hypertensive by wrapping the kidneys according to the Page method, hypertension was relieved by a portacaval shunt, the anastomosis of the portal circulation to the vena cava reducing venous pressure. Among the persons with emphysema and bronchial asthma there were many with myocardial infarction. The authors believe that this is explained by impaired venous coronary return to the right auricle in the presence of increased intrapleural pressure. The existence of cor pulmonale is a further impediment to coronary outflow. It is significant that both the hypertension and the asthma, and particularly the asthmatic attacks, may improve when these patients are digitalized or given coronary dilators, such as aminophylline. Finally, myocardial damage, with or without hypertension, as well as mild chronic anoxemia in patients with severe long-standing emphysema, explains left along with right ventricular hypertrophy that is found at autopsy in such patients.

The Hamman-Rich Syndrome.—Peabody and associates show that as experience with the Hamman-Rich syndrome has increased, it has become obvious that the term acute diffuse interstitial fibrosis of the lungs is both inaccurate and cumbersome. Various reports established the existence of chronic forms of the disease. Moreover, since the word fibrosis refers to the end-result, it would probably be better to speak of diffuse fibrosing interstitial pneumonitis. This term likewise is unwieldy, but more concise appellations, such as cirrhosis of the lung and idiopathic pulmonary fibrosis, lack specificity. For these reasons, the authors refer to these cases as the Hamman-Rich syndrome, which they define as an acute or chronic pulmonary disease of unknown etiology characterized clinically by cough, dyspnea, and cyanosis in association with minimal physical findings and a progressive, essentially afebrile course. The roentgenologic appearance conforms to no set pattern. The most distinctive feature is the microscopic appearance. The pulmonary interstitial tissue is pervaded by a profuse fibrous reaction varying from a proliferation of young fibroblasts to the deposition of large quantities of hyalinized connective tissue. Intermingled with the fibrous elements are numerous chronic inflammatory cells, consisting predominantly of lymphocytes and plasma cells, with a few macrophages and occasionally a number of eosinophils. Except for the administration of oxygen and symptomatic care, little can be done for these patients. Although the authors witnessed a most dramatic demonstration of the potential value of cortisone and corticotropin in the management of the Hamman-Rich syndrome, they remain impressed with the limitations and dangers of hormonal therapy. In three patients, a violent exacerbation of their pulmonary disease developed, in two after withdrawal of cortisone and in the other after a decrease in corticotropin dosage. All three died. The authors stress that patients with asymptomatic or mildly symptomatic diffuse indeterminate pulmonary disease should not be subjected to endocrine treatment, since the course is relatively benign. Patients with long-standing disease should probably not receive cortisone or corticotropin, since fibrosis precludes any significant improvement. If hormone therapy is decided upon, preferably in the early severe case, streptomycin should be administered concomitantly. No matter how slowly the hormone agents are interrupted serious withdrawal symptoms can be anticipated and, for that reason, once endocrine therapy has been instituted it would seem advisable to continue its use indefinitely. When withdrawal is tried, cortisone must be interminably continued so that the adrenal cortex will gradually resume its function, an effect augmented by small doses of corticotropin. At the first sign of an unfavorable trend, both cortisone and corticotropin should be reinstituted in large doses along with broad spectrum antibiotic therapy.

Periodicals on file in the Library of the American Medical Association may be borrowed by members of the Association or its student organization and by individual subscribers, provided they reside in continental United States or Canada. Requests for periodicals should be addressed "Library, American Medical Association." Periodical files cover only the last 11 years, and no photoduplication services are available. No charge is made to members, but the fee for other borrowers is 15 cents in stamps for each item. Only three periodicals may be borrowed at one time, and they must not be kept longer than five days. Periodicals published by the American Medical Association are not available for lending but can be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them.

Titles marked with an asterisk (*) are abstracted.

Ultraviolet Radiation and Vision.—Ultraviolet radiation refers to the spectral region from approximately 300 to 400 m μ ; in other words, the near ultraviolet rays. In many textbooks the visible spectrum is said to end at 400 m μ , and the I.C.I. (International Commission on Illumination) luminosity curve does not extend beyond 380 m μ , but shorter wave lengths than this have been reported to be visible on several occasions. The wave lengths of about 300 m μ produce erythema and photophthalmia in the eye. Although the shorter wave lengths cannot penetrate to the retina, those between 300 and 400 m μ can have a harmful effect on vision. This paper discusses the visibility of the band of the spectrum and its possible effects upon visual function. In youth, the eye is reported to be sensitive to wave lengths down to 300 m μ , but the limit of the visible spectrum is higher in old age, owing to the increased absorption of the lens. Differences in lens absorption also lead to wide individual differences in sensitivity to ultraviolet radiation, but there are no data for the absorption of the human eye in the ultraviolet region of the spectrum. It has been claimed that exposure to ultraviolet radiation will impair dark adaptation, but the weight of evidence is against this view. Wave lengths above 305 m μ have no abiotic effect; consequently, any changes in the threshold would seem to be due to the light adaptation of the eye. Under the action of ultraviolet rays, the lens will fluoresce strongly, and the intensity of the fluorescence increases with age. Little or nothing is known of the effect of fluorescence on visual function. There is disagreement about the color sensation produced by ultraviolet radiation, but in most cases it is stated to be blue or blue-violet.

Muscle Changes in Poliomyelitis.—Aronson and Schwartzman point out that the search for reproducible extraneural lesions in the course of experimental poliomyelitis has been consistently unfruitful. Schwartzman, however, had demonstrated that cortisone potentiates the paralytic morbidity and the mortality of the Syrian hamster infected with type 2 poliomyelitis virus. After such enhancement of the experimental disease, visceral lesions, including myositis, appear. The present report is concerned with histological studies on such muscle lesions. The poliomyelitis virus used was the MEF₁ strain, and male Syrian hamsters weighing 20 to 28 gm. were employed in all experiments. A florid necrotizing myositis developed in the animals that had been pretreated with cortisone. The micro-

scopic lesions are characterized by rapidly progressing hyaline degeneration, loss of striations, edema, extensive necrosis, and mineralization. The microscopic picture is similar to that evoked by other neurotropic viruses in experimental animals. Evidence is presented elsewhere that there is a proliferation of the poliomyelitis virus in such sites.

Surgical Treatment of Mitral Stenosis.—Surgical relief of mitral obstruction was practiced in 17 men and 58 women with mitral stenosis between the ages of 20 and 49 years. These 75 patients were selected because of genuine and progressive circulatory disability associated with cough, paroxysmal nocturnal dyspnea, attacks of pulmonary edema after exertion or at rest, and hemoptysis. Of the 75 patients, 34 had excellent results from the surgical intervention, 17 good results, and 13 fair results. In two the procedure was a therapeutic failure, and nine died. Four deaths resulted from embolism, four from progressive cardiac failure and one from staphylococcal pericarditis. Considerable and sometimes dramatic improvement occurred in 51 patients and persisted in most of those followed up for three years or more. Clinical improvement in these patients must depend on the improved ability to increase the flow of blood through the lungs with exertion, without causing congestion in the critical capillary area. The physiological measurements so far applicable during exercise do not serve adequately to explain the subjective improvement of these patients. The capacity to withstand the physical stress of living is still the most informative test in this regard. The two most devastating complications are embolism at operation and reactivation of rheumatic carditis. The former is a surgical problem. The latter occurred in 5 of the 66 surviving patients; it calls for the most thorough application of the only known methods of preventing rheumatic fever—prophylaxis against Streptococcus infections of the respiratory tract with sulfadiazine or penicillin or, failing this, the prompt initiation of antibiotic therapy at the onset of respiratory infection. The need for surgical relief of mitral stenosis is determined by rheumatic fever. The ultimate success of this procedure will likewise depend on the subsequent control of that disease.

Hypotensive Anesthesia.—Hypotensive anesthesia was used in the past two years in 16 male and 98 female patients on whom various pelvic and abdominal operations, such as radical hysterectomy and node dissection, total or partial pelvic exenteration, pancreato-duodenectomy, partial hepatectomy, hemipelvectomy, resection of pelvic or abdominal tumors, major orthopedic operations, total vulvectomy, bilateral adrenalectomy, radical mastectomy, and thoracoabdominal gastroesophagectomy, were performed. The patients were selected for clinically unimpaired cardiovascular, renal, and respiratory functions. After proper premedication, the patient was given

thiopental (Pentothal) sodium intravenously, supplemented by tubocurarine chloride, and a plastic endotracheal tube of adequate bore was introduced orally. The tube was then attached to an ether-oxygen absorption circle and the patient placed in proper position. For pelvic surgery, a head-down tilt of about 30 degrees, with knees acutely bent, is sufficient, and, although the operative field is not the highest point, the postural ischemia produced in this way, proved to be satisfactory for all clinical purposes. The supine jackknife position was used for upper abdominal surgery (liver and pancreas). Here the head-down principle was preserved, and a maximal postural drainage of blood from the operative field was achieved. A semilateral jackknife position is recommended for thoracoabdominal approaches. After positioning of the patient, the blood pressure was reduced by intravenous administration of hexamethonium bromide in doses ranging from 10' to 100 mg. The systolic blood pressure dropped to 65 to 70 mm. Hg in most patients and was maintained at that level with additional doses of the drug, if necessary. It is desirable to maintain the hypotensive state for not longer than 75 to 100 minutes. After the excisional surgery was completed, the blood pressure was brought back to about 100 mm. Hg by elevating the legs, changing the patient's position to almost horizontal, and by infusing phenylephrine (Neo-Synephrine) hydrochloride or another vasopressor agent of a dilute solution. During this type of anesthesia the anesthesiologist must be constantly on the alert to observe for proper oxygenation and changes in blood pressure and pulse and to correct blood loss. While the blood pressure could not always be lowered to a satisfactory level in young adults, satisfactory results were obtained in the patients between the ages of 45 and 60 years. The recovery time was not prolonged, and the incidence of vomiting seemed reduced. Not only the blood loss was reduced but also concomitantly the tissues were more exactly dissected; principal blood vessels were more easily and clearly visualized for isolation and dissection, and insofar as cancer surgery is concerned, areolar tissues and lymph nodes were dissected en bloc in a more satisfying manner than is the case under ordinary anesthesia at usual blood pressure levels. Hypotensive anesthesia is still under investigation, and impaired cardiovascular, renal, and respiratory functions represent, so far, a definite contraindication for this technique. The author feels that hypotensive anesthesia has a place in selected cases in radical surgical procedures for advanced cancer.

Management of Remaining Common Duct Stones.—Best and co-workers studied the solvent action of various types of solutions or combinations with equal parts of chloroform or ethyl ether on gallstones. Solvent experiments carried out *in vitro* showed that chloroform and ether were effective on all stones containing cholesterol. Chloroform was somewhat superior. Mixed stones responded better to chloroform, and in some cases the addition of a fatty acid in a 1% solution to chloroform and ether increased the fragmentation and dissolution. Lauric, caprylic, and linoleic acids were most effective in this regard, but were never of sufficient value to justify their use. Heated chloroform was consistently much more effective than chloroform of room temperature. For the purpose of evaluating the effect of chloroform on liver and ductal tissue, the drug was instilled through a small polyethylene tube into the biliary tract of dogs. Nine dogs received injections, and seven had only the polyethylene tube inserted for control purposes. The animals were killed at intervals of from 5 to 30 days. At necropsy there was minimal gross change in the liver and ductal tissues in both groups. Microscopically there was essentially no injury to the ducts in either group. There was slight to severe liver damage in the form of central lobular necrosis in both groups. Ten patients with proved choledocholithiasis were subjected to chloroform instillations. Four to 5 cc. of chloroform heated to 60 C was injected in the side arm of a double lumen T-tube on two successive days. Most of the patients complained of some nausea and a little distress, and a few stated the nausea lasted for several hours. Only one patient complained of severe nausea and pain; she was a very nervous, uncooperative patient in whom the authors questioned using the procedure. The remaining patients tolerated the chloroform well and with no ill effects. A simplified three day biliary flush regimen was carried out in 14 patients in whom

the postoperative choledochogram revealed a remaining common duct stone. On the first and second days of the biliary flush regimen 4 to 5 cc. of chloroform heated to 60 C was instilled into the side arm of a new type, wide angle, double lumen T-tube that directed the solution away from the liver toward the duodenum and the portion of the common duct where remaining stones are usually seen. On the third day, 5 cc. of ethyl ether was slowly instilled into the T-tube, releasing pressure or drawing back on plunger to help control intraductal pressure that gave rise to any distress. Glyceryl trinitrate, 1/100 grain (0.6 mg.), was given sublingually five minutes prior to the instillation of ethyl ether. There were two failures. In the other patients (80%), the remaining common duct stones were successfully dislodged. Since it is known that stones or debris are frequently present in the common duct when choledochostomy has not been done, the three day flush regimen is recommended after every cholecystectomy. This is usually prescribed about one week postoperatively and is repeated two weeks later. By this method one is able to almost eliminate return of those symptoms presented before operation.

Heredity in Resistance to Pulmonary Tuberculosis.—A 10 year follow-up study was conducted on 43 monozygotic and 30 dizygotic pairs of twins in which both twins of each pair had chronic pulmonary tuberculosis and on 40 monozygotic pairs in which only one twin was affected. Intra-pair similarities and dissimilarities in the initial stage, subsequent course, and clinical outcome of the disease were analyzed. The influence of certain modifying factors, namely adequacy of hospitalization, differences in life conditions, and nonspecific constitutional factors, was considered. It was found that simultaneous onset of the disease was more frequent in the monozygotic than in the dizygotic pairs. The extent and pathological character of the initial lesions (at time of diagnosis) also were more frequently similar in the monozygotic than in the dizygotic pairs. In the monozygotic pairs, the clinical outcome was similar or dissimilar in about equal proportions. In most pairs the dissimilarity was between fatal outcome in one partner and arrest of the disease in the other. This indicates that even when one twin died of tuberculosis his genotypically identical partner had a statistically fair chance of survival with arrested disease. In the majority of monozygotic pairs with similar clinical outcome, the onset was simultaneous. While prompt and regular hospitalization was the rule in the arrested cases and inadequate hospitalization was noted in most of the fatal cases, an unequivocal causal relationship could not be established between clinical outcome and adequacy of treatment. In the monozygotic pairs discordant as to tuberculosis a high level of resistance has been suggested by the prevalence of the tendency to repair in the tuberculous lesion and by the preferential development of tuberculosis in those twin partners in whom other pathological conditions were found, preceding or concomitant to tuberculosis.

Retrolental Fibroplasia Produced by Oxygen in Animals.—Patz and associates point out that in a nonrandom study conducted in the premature nursery of the Gallinger Municipal Hospital between July, 1948, and January, 1951, a striking

correlation between duration of oxygen therapy and incidence of both mild and severe retrolental fibroplasia was noted. A controlled random study was instituted to evaluate critically the role of oxygen therapy. The results of this controlled nursery study conducted between January, 1951, and May, 1953, supported the previous observations and justified the conclusion that prolonged high oxygen administration is an important factor in the development of retrolental fibroplasia. Parallelizing the nursery study an extensive investigation was started to evaluate both the ocular and systemic effect of oxygen on several species of animals. By exposing newborn rats, mice, kittens, and puppies to 70 to 80% oxygen concentration for varying periods of time, changes in the eyes closely resembling human retrolental fibroplasia resulted. The characteristic endothelial nodule in the nerve fiber layer of the retina, with budding of vessels through the internal limiting membrane into the vitreous, and retinal hemorrhages were produced. The mouse and the kitten proved to be the most satisfactory laboratory animals for this study. On the basis of clinical and experimental observations, the authors make the following recommendations (1) a rigid curtailment of oxygen therapy, compatible with the physical status of the premature infant, should be practiced in the nursery; (2) to insure this, an accurate oxygen analyzer should be standard equipment in every premature nursery; (3) frequent samples of oxygen tension should be taken when oxygen is administered; (4) except for emergency use, oxygen therapy should require a specific order; (5) oxygen should be ordered by concentration rather than by flow rate.

Management of Acute Gastroduodenal Perforations.—Miller and co-workers have evaluated data derived from their study of 195 cases of acute gastroduodenal perforation. The 89 patients observed between 1930 and 1941, inclusive, had been reviewed in 1943. The present study includes an additional series of 106 patients with acute gastroduodenal perforations, who were treated at the same hospital during the nine year period from 1942 to 1951, inclusive. By comparing these two groups the authors endeavor to evaluate the efficacy of their therapeutic methods. It was found that perforation of gastro-duodenal ulcer is occurring in older patients and in women with increasing frequency. Whereas in the earlier group of patients 96% of the patients were men, in the later group only 84% were men. Signs and symptoms of perforation may

be less typical in the elderly and in women; however, a higher index of suspicion should bring these patients to surgery earlier and should result in a reduction of the present high mortality rate. The choice of treatment must be governed by a careful appraisal of the several factors. Simple plication remains the method of choice in most instances, particularly when perforation is the first indication of ulcer disease or when the history is of short duration. The older patient is most safely treated by simple plication. Immediate partial gastrectomy is indicated when spontaneous gastroduodenal hemorrhage and perforation coexist and is the treatment of choice when the perforation occurs through a malignant lesion. Immediate gastric resection should be considered seriously when there is a perforated gastric ulcer in a female patient. It is advisable that the following criteria are met before proceeding with subtotal gastric resection: (1) the patient in good constitutional condition and less than 50 years of age; (2) perforation of less than 12 hours' duration; (3) no sign of clinical shock; (4) no evidence of extensive peritonitis; and (5) operative and anesthetic facilities comparable with those available for an elective gastrectomy. Conservative treatment is best employed when the perforation has been present for more than 24 hours, in the presence of severe shock, or in the presence of severe constitutional disease.

Patent Ductus Arteriosus with Reversed Blood Flow.—The first case of a successful surgical closure of a patent ductus arteriosus with reversal of normal blood flow is reported. The patient, a 36-year-old man, entered Wadsworth General Hospital of the Los Angeles Veterans Administration Center in September, 1952, complaining of shortness of breath and pain in the chest after an alcoholic episode. His history revealed other cardiac disturbances that had been ascribed to rheumatic fever. Examination revealed a Graham Steell murmur secondary to severe pulmonary hypertension and other signs that led to the diagnosis of patent ductus arteriosus with reversed blood flow. It appeared that the right-to-left flow in the shunt could be reversed by means of small alterations in the degree of pulmonary vascular resistance; the greater and lesser circula-

tions seemed to be critically balanced in this case. At operation, the ductus was sutured, but not divided. There were various postoperative complications, but by the 10th postoperative week, the patient was ambulatory and showed great subjective improvement. He left the hospital permanently without permission before clinical signs of a change in pulmonary arterial pressure appeared. Six weeks after his untimely departure, the patient wrote that he had returned home. The authors feel that, when possible, an anomaly of this type should be corrected surgically, to spare the patient an inactive life with early death. The factors to be considered in deciding upon surgery are presented.

Fat Necrosis After Hypothermia.—Induced hypothermia was employed in a surgical operation lasting 2 hours and 25 minutes for a tetralogy of Fallot in a 4½-month-old boy. He was discharged from hospital in good condition 14 days postoperatively, but, in the following six days, slight blue, raised, hard areas developed in the skin of various parts of his body. These lesions were of an inflammatory nature and were accompanied by pain and low grade fever. Biopsy showed evidence of an intact dermis with subcutaneous fat necrosis. The condition improved with the administration of corticotropin and oxytetracycline, but three days after the second discharge the patient had an acute episode of screaming, ashy cyanosis, and posttation. After four more of these attacks, which showed no signs of cardiac failure but resembled severe angina pectoris in adults, the baby died. Autopsy permission was not granted. The authors are of the opinion that the fat necrosis was caused by the exposure to cold, but that the patient's death did not necessarily result from this condition. They do not wish to condemn controlled hypothermia as an aid to cardiovascular surgery.

Renal Vascular Disease in Diabetes Mellitus. E. T. Bell.—p. 376.

Renal Vascular Disease in Diabetes Mellitus.—Bell's microscopic study of the kidneys of 688 diabetic male and 777 diabetic female patients on whom necropsies were performed demonstrated that renal arteriosclerosis is more frequent and severer in diabetes than in primary hypertension. Of the 1,465 patients, 33 were less than 20, 234 were between the ages of 20 and 50, and 1,198 were over 50. Renal arteriosclerosis was observed in about one-half of those between 20 and 50 years and in nearly two-thirds of those past the age of 50. The highest incidence was in elderly women. It was not due to hypertension since it was observed in over one-half of elderly nonhypertensive diabetic patients. It appears to be caused by the diabetic state, and in young diabetic patients it is largely responsible for the development of hypertension. The incidence of arteriosclerosis increases with the duration of diabetes, particularly in young patients. Hypertension was present in 60.9% of the diabetic men and in 67.8% of the diabetic women over 50 years of age. Presumably the hypertension of elderly diabetics is chiefly of the primary type; that is, a majority of them present an accidental association of diabetes and primary hypertension. Nodular intercapillary lesions were observed in 12.8% of the 688 diabetic males and in 19.4% of the 777 diabetic females. The frequency of intercapillary lesions increases with the duration of diabetes, particularly in younger patients. In diabetics under 50 years of age intercapillary lesions are much more frequent in hypertensive persons, but after that age the relation to hypertension is much less prominent. Satisfactory qualitative examinations for proteinuria were made at the last hospital admission in 897 of the 1,465 patients; the clinical data and the necropsy observations were reviewed in all of the diabetics who had edema of any degree. Intercapillary lesions may be present when proteinuria is mild or completely absent, but a severe proteinuria suggests the presence of the glomerular lesions, particularly in younger diabetics. Severe edema in a diabetic under 50 years of age is usually of renal origin and strongly suggests the presence of intercapillary glomerulosclerosis, but in the older diabetics edema is of much less diagnostic value with respect to the presence of a renal lesion since it is usually due to cardiac failure or other causes. The nephrotic syndrome, rigidly defined as proteinuria of 2+ or more and edema 2+ or greater, developed in 26 (45.6%) of 57 patients with intercapillary glomerulosclerosis aged less than 50 years and in 42 (14.9%) of 282 aged over 50. Intercapillary glomerulosclerosis is, therefore, not a distinct entity in the sense that it usually produces a recognizable clinical syndrome. Renal insufficiency, usually clinical uremia, occurred in 36 (63%) of the 57 patients with intercapillary glomerulosclerosis aged less than 50 years and in 80 (26%) of 308 aged over 50. Renal insufficiency in a diabetic patient is due chiefly to arteriosclerosis and intercapillary glomerulosclerosis. Renal insufficiency in primary hypertension is due largely to obstruction of the small renal arteries in the absence of primary glomerular lesions and with arteriosclerosis being inconspicuous. In diabetics aged less than 50 years the presence of intercapillary glomerulosclerosis is strongly indicated by severe proteinuria, severe edema, hypertension, or retinitis; but after the age of 50 these symptoms and signs have much less diagnostic significance.

Röntgenologic Considerations of Gastro-Intestinal Bleeding. R. D. Moreton.—p. 523.

Vaginal Discharge. J. B. Traylor.—p. 529.

Vaginal Discharge.—Traylor discusses 12 different causes of abnormal vaginal discharge. In the presence of cancer of the cervix, fundus, vulva and vagina, the discharge may be serous, purulent, sanguineous, or any combination thereof. Inspection of the vulva and vagina may disclose an ulceration. A dark field examination is imperative, and, if the results are negative, a biopsy should be performed. A syphilitic chancre may occur on any part of the genitals and may be confused with cancer or any of the other ulcerative venereal diseases. Tuberculosis also may appear as an ulceration on the genitals and tends to form sinuses. The discharge may be watery or bloody at first and later caseous. Chancroid, lymphopathia venereum, and granuloma inguinale do not occur as commonly as the three diseases previously described, but they must be considered in the differential diagnosis of ulcerative lesions of the lower portion of the genital tract. Skin tests with Ducrey antigen and the Frei test are useful in making the diagnosis of chancroid and lymphopathia venereum. Donovan bodies are found in tissue smears taken from lesions of granuloma inguinale. The most frequent cause of vaginal discharge is Trichomonas vaginalis. When Trichomonas infection is suspected, the speculum is inserted with no lubricant, and a small amount of the discharge is gathered on an applicator and placed in 1 cc. of isotonic sodium chloride solution. Examination of a drop of this suspension under the microscope will disclose the flagellated organisms. The diagnosis of the next most frequent cause of vaginal discharge, moniliasis, is made by fixing a similar preparation to that used for the diagnosis of Trichomonas. In the wet smear the finding of mycelial threads verifies the diagnosis. In ovulatory bleeding the pain and spotting can usually be controlled by the oral administration of 10 mg. of methyl testosterone for 20 days, beginning on the first day of a menstrual cycle. Thyroid extract is helpful in the treatment of

Cortisone and Corticotropin for Allergies.—Of a large group of ambulatory patients with bronchial asthma and allied allergies treated with cortisone or corticotropin (ACTH), 18 with bronchial asthma and 9 with allergic dermatitis were selected as representative. The causative factors included inhalants, contactants, ingestants, and infections. Severe cases of bronchial asthma or dermatitis required an initial dose of cortisone of 200 mg. daily for the first few days. On improvement this dose was reduced to 100, 75, 50, and 25 mg., with a final maintenance dose as low as would keep the patient symptom-free, usually 12.5 mg. daily or every other day, accompanied by 10 or 20 units of corticotropin gel once or twice a week. Less severe cases responded well to initial daily doses of 100 or even 75 mg. of cortisone, reduced gradually to a low maintenance dose of 12.5 mg. every two or three days, usually with, but sometimes without, the addition of corticotropin gel. Excellent results were obtained in all but 3 of the 18 patients with asthma and in all 9 patients with allergic dermatitis. In only one patient was there a true therapeutic failure; in the other two, good or fair results were achieved initially, but the patients did not continue with the treatment. Remission of symptoms usually was maintained by the application of standard therapy, such as removal of the patient from specific irritants, change of diet, elimination of infectious foci, and immunization, plus small maintenance doses of cortisone orally supplemented by corticotropin gel. Complete or sudden discontinuance of the steroid hormones should be avoided to guard against the exhaustion state. Tapering off can best be accomplished first by a gradual reduction in the daily dose, then by an increased interval between doses. Side-reactions were infrequent, and in only three patients were

they serious enough to call for withdrawal of the hormones. While the mode of action of cortisone and corticotropin in allergy is not known, their clinical usefulness in bronchial asthma, pollen asthma, and allergic dermatitis is well established. However, there is no evidence that the hormones influence the further course of allergic diseases or that either arrest or complete cure is achieved after they have been discontinued. It is only when maintenance therapy is continued for long periods, that the benefits are lasting for many months to more than one year. Clinical symptoms recur sooner or later after the hormones have been completely withdrawn, unless the irritating factor is eliminated.

Anaphylactic Shock After Penicillin Therapy.—Anaphylactic shock occurred in nine patients with bronchial asthma who had received daily injections of 300,000 units of penicillin G or procaine penicillin. One patient was sensitized after 12 injections, two after 18 injections, four after 26 injections, and two after 54 injections. All of the patients noticed some symptoms after the one or two injections that preceded the shock-eliciting injection but did not consider them severe enough to mention. Syncope, mild to severe, at the time of the injection or a feeling of faintness recurring periodically for the following three to four hours, sensation of burning or heat throughout the body, local or generalized pruritus never before present, choking sensation in the throat, with increasing cough, dyspnea and wheezing, and severe paroxysmal pain, such as precordial, epigastric, or diaphragmatic, are the signs and symptoms by which one can be forewarned of anaphylactic shock and refuse further parenteral penicillin therapy. In the emergency of a shock reaction, the greatest immediate aid may be obtained with small doses, 0.12 to 0.2 cc., of epinephrine solution (1:1,000) given intradermally every two minutes until the patient is out of danger, usually 15 or 20 minutes, or beyond help. Although anaphylactic shock after penicillin injection in bronchial asthmatics is not common, one must be alert for it because of its severity when it does occur. Three illustrative cases in men between the ages of 49 and 59 are described.

Giant Cell Tumors of Bone.—The occurrence of a large giant cell tumor of bone is reported in a 51-year-old woman and in a 36-year-old man. Roentgenograms showed a destructive, expansile lesion in the lateral condyle of the left femur in the woman and a tumor of the left ilium in the man. Roentgen irradiation was administered to both patients and resulted in extensive damage to skin, muscles, and other soft tissues sur-

rounding the tumors, with only partial destruction of the tumor. The tumors continued to grow in both patients and required much more extensive surgery than would have been adequate if it had been performed when the diagnosis was first made. Giant cell tumor of bone should be differentiated from all other lesions that also contain multinuclear giant cells, including solitary bone cyst, nonosteogenic fibroma, aneurysmal bone cyst, chondromyxoid fibroma of bone, benign chondroblastoma, and the "brown tumors" sometimes observed in hyperparathyroidism. The giant cell tumor of bone is clinically, anatomically, and cytologically a distinctive neoplasm. The pathologist who depends entirely on the microscopic examination and ignores the clinical history and roentgenographic examination will make many errors of diagnosis. Irradiation as a primary or total plan of treatment of giant cell tumors of bone is neither certain to cure nor free from danger. The larger giant cell tumors cannot be destroyed by irradiation without severe damage to the adjacent tissues. Most giant cell tumors may be adequately and safely treated by surgery followed, in some instances, by irradiation therapy.

Reticulum Cell Sarcoma of Bone.—In a survey of 2,000 specimens of primary tumor of bone preserved at the division of surgical pathology of the Mayo Clinic between 1905 and 1952, 49 were found to be reticulum cell sarcomas. Of 29 patients with solitary lesions in whom the condition was diagnosed in 1947 and earlier, 10 (35.7%) survived. This five year survival rate is somewhat better than the rate for most other primary malignant bone tumors, but is distinctly lower than the rate reported by Coley and his associates. Of the smaller group of 10 patients who presented multiple lesions on admission, 8 are known to be dead. Of these eight patients, three (37.5%) lived five or more years after the diagnosis was made. The survey reinforced the authors' conception that reticulum cell sarcoma is a firmly established entity. It is important to establish the diagnosis by adequate biopsy. Unlike most other primary malignant conditions of bone, reticulum cell sarcoma appears to be radiosensitive and, in one case in which the tumor disappeared, administration of Coley's toxins was the only treatment. At present, it appears that the prognosis in cases of reticulum cell sarcoma of bone is significantly better than that in most other primary malignant tumors of bone. Concerning treatment, the authors believe that amputation or radical excision followed by roentgen therapy locally and to regional lymph nodes offers the patient the best chance of survival; in recent months administration of Coley's toxins had been added to treatment.

Influence of Dietary Fat on Growth and Longevity.—French and associates point out that groups of investigators have shown that high fat diets are superior to low fat diets for growth, efficiency of food utilization, and physical capacity. There is little information, however, regarding such a comparison on a life span basis. The possibility that high fat diets may have a detrimental effect on length of life and that they may promote the development of degenerative disease in the aged, although often expressed, has little experimental evidence for its support. Carlson and Roelzel reported in 1947 that rats fed an omnivorous diet containing 28% fat and 35% protein lived somewhat longer, on the average, than those receiving a vegetarian diet containing about 8% fat and 30%

protein. It is interesting to note, however, that only one rat lived more than 1,000 days on the omnivorous diet, while four in the vegetarian group exceeded this age at death. Life span was more uniformly prolonged by intermittent fasting in the case of the rats receiving the omnivorous diet. French and co-workers report experiments with three different diets carried out over a period of four years. For some of the details of their studies they refer to a report made in 1952. Male and female rats receiving a high fat diet (22.7% fat) grew as rapidly as those receiving a carbohydrate diet (3.4% fat), although they consumed 4.8 and 5.7% less total calories, respectively. No seasonal variation in food consumption occurred in any of the diets fed. The life span of male rats ingesting the high fat diet decreased markedly, and there was also a less pronounced but significant decrease in the longevity of the females. Increased efficiency of utilization of the diet was correlated with decrease in life span, but increased caloric intake per se was not so associated. The livers of males on the high fat diet contained significantly more fat than of males fed the carbohydrate diet. The histological data and the frequency of diseases and nothing that could be interpreted as a fat-induced cause of premature death.

Boric Acid Poisoning.—Four cases of boric acid poisoning are described in infants between the ages of 13 and 20 days. In all four, poisoning resulted from topical application of boric acid preparations to the buttocks. In one patient a popular brand of baby powder containing the active ingredients talc and boric acid was the source of the toxicity. In 109 cases of boric acid poisoning (105 collected from the literature and the authors' 4 cases) the over-all mortality was 55%, and the mortality in patients less than one year of age was 70.2%. Data obtained from analysis with respect to age, route of intoxication, signs and symptoms, necropsy findings, and chemical analyses of body organs for boric acid were correlated with the results of experimental boric acid intoxication. The high degree of absorption of boric acid from broken skin surfaces and mucous membranes is emphasized. Absorption of boric acid through intact adult skin could not be demonstrated, confirming the findings of Pfeiffer and associates in this regard. The particular sensitivity of young infants to the toxic effects of boric acid is noted, and the importance of recognizing milder cases of poisoning in this age group is stressed. The common clinical findings consist of erythematous skin eruptions, followed by desquamation, diarrhea and vomiting, and evidence of meningeal irritation. The presence of boric acid in the urine and spinal fluid is readily confirmed by use of the turmeric-paper

test. The authors recommend that, since boric acid is a potentially dangerous drug, possessing only mild bacteriostatic activity, its use in any form of medical therapy, particularly as applied to infants and children, be discontinued.

Transcutaneous Absorption of Boric Acid.—Transcutaneous absorption of boric acid is described in three infants between the ages of 27 days and 4 months treated for diaper rash with a commercial borated talc followed by boric acid powder for seven days and boric acid ointment applied for one week followed by bathing in boric acid solution and dusting of the skin with boric acid crystals intermittently for two weeks, respectively. One child died. The diagnoses were made on clinical grounds and corroborated by laboratory analysis of blood, urine and cerebrospinal fluid. In one of the patients the level of boric acid in the blood was determined by chemical analysis to be 5 mg. per 100 cc. of blood. The total amount of boric acid in the circulation would thus be 17.5 mg., assuming the blood volume to be approximately 350 cc. As this infant was dying, it would appear that this figure is close to the fatal blood level. It was calculated that owing to the transcutaneous absorption of boric acid from solution resulting from 5% borated talc in contact with the infant's urine, the lethal amount of 17.5 mg. may be reached in only five days (of 10 daily applications of the borated dusting powder during diaper changes) over the relatively small excoriated area of 100 square centimeters if only 1% of the available boric acid accumulates in the blood stream. In view of the insidious nature of boric acid poisoning and the facility of its transcutaneous absorption it seems likely that further morbidity will result unless its use is discontinued in favor of other more efficient and safe antibacterial agents.

Cerebrospinal Fluid and Serum Studies in Measles Encephalitis.—During the 1952 epidemic of measles, 41 patients with measles encephalitis and encephalomyelitis were successfully treated with large doses of gamma globulin and adjunctive therapy in the acute phase. The results of this therapy were reported in a previous paper. The adjunctive therapy included an adequate supply of the metabolites phosphorus, cholesterol, and magnesium, which are not usually considered in measles encephalitis and encephalomyelitis; such a supply is essential during the period when catabolism is reverting to normal metabolism and when destroyed central nervous system tissue is being repaired. This type of adjunctive therapy presented the application of the results of the authors' studies of the cerebrospinal fluid and serum in the 41 patients in the acute phase of measles and encephalomyelitis. Abnormal inorganic phosphorus values were revealed both in the cerebrospinal fluids and serums of these patients. A greatly increased level of inorganic phosphorus in the cerebrospinal fluid was observed in 8 out of 12 patients, while the serum showed hypophosphatemia in 9 out of 11 patients resulting in an abnormal ratio of cerebrospinal fluid inorganic phosphorus to serum inorganic phosphorus. The inorganic phosphorus values of the cerebrospinal fluid ranged from 1.7 to 4.1 mg. per 100 cc. The mean was 2.02 mg. per 100 cc., with a standard error of the mean of ± 0.11 . When compared to a series of control patients previously reported, this increase was found to be statistically significant. In addition, abnormally high total cholesterol values were found in the cerebrospinal fluid of three patients in the acute phase of the infection. These observations can be correlated with the pathological findings in measles encephalitis and encephalomyelitis. Microscopic examination revealed diffuse perivascular demyelination (destruction of phosphorus-containing tissue), and varying quantities of fat both in the phagocytic glia cells and in the surrounding tissues were almost always present. The role of magnesium in viral infections with complications in the central nervous system and its use in therapy was assessed. Also an unusually high percentage (94%) of the cerebrospinal fluids from the authors' patients with measles encephalitis and encephalomyelitis revealed pleocytosis, elevated total protein, or both. The characteristic leukocyte count in patients with measles encephalitis and encephalomyelitis is that of an acute infection with an elevation of the leukocyte count with a tendency toward a relative granulocytosis. Where the white blood cell count remains normal, a relative

lymphocytosis predominates. The serum constituents, glucose, total protein, albumin-globulin ratio, chlorides, urea nitrogen, sodium, potassium, calcium, and cholesterol, were, except for a few instances, within normal limits during the acute stage of the disease. Slight acidosis was observed in most patients on admission.

Tuberculosis Case Finding in Schools.—Ayling, health director of the public schools in Syracuse, N. Y., questions the desirability of tuberculosis case finding programs in the schools. He feels that it is a mistake to look for tuberculosis only in persons over age 15. Of the 45 cases of active tuberculosis found in the last six years by the author's staff or other agencies screening school children 36, or 80%, were in children 15 or under. Furthermore, tuberculosis is still the leading cause of death from disease in the age group 15 to 35. Undoubtedly many of the deaths are the result of tuberculosis that started when the persons were less than 15 years old. Ayling shows that there is a trend back to the use of the tuberculin test for case finding. He quotes among others the spokesman for the American Trudeau Society as saying that, "In areas with low rates of tuberculosis infection tuberculin testing with x-ray examination of positive reactors is of greater practical value than mass surveys." The author presents arguments against the use of BCG and points out that in 1949, complying with a request from the local health department, BCG was given to all children who had negative tuberculin reactions in two schools that were in an area where the incidence of tuberculous infection among adults was higher than in any other part of the city. It was thought that the BCG would give some protection to these pupils. It was necessary to get parental consents for (1) a tuberculin test, (2) a chest film, (3) administration of BCG, and (4) another tuberculin test two months later to determine "takes." A great deal of time and effort was involved in this program. BCG was given to 834 pupils who had had negative reactions and normal roentgenograms. In the tuberculin test given two months later 690 had positive reactions. One year later 524 were retested and 90 had reverted to negativity. Each year since then it has been found that more and more of these pupils have negative reactions, that is, any protection they may have had did not persist very long. One could never be sure that a child who had been given BCG was not acquiring active disease except by making roentgenograms of all these with positive reactions each year. In one boy who had been given BCG active tuberculosis did develop. Now it is realized that it was a mistake to give BCG to these school children mainly because it upset the regular case finding program. It also was a time consuming task and a disagreeable one as far as the children were concerned. The author concludes that a tuberculosis case finding program using the tuberculin test is valuable.

Experimental Closure of Atrial Septal Defects.—An ideal method for the surgical closure of atrial septal defects in human patients would be applicable to defects of all types and sizes, would give reasonable assurance of complete closure of the defect, preferably with autogenous tissue, and would be capable of being accomplished in a dry field without loss of blood, without interference with cardiac function, without the necessity of using anticoagulants, and without the hazard of air embolism or intracardiac thrombosis. Various methods of closure were used in repairing large atrial septal defects created in healthy dogs either immediately before the closure or at some time previous to it. An autogenous graft was applied directly to the defect through the opened right atrium during temporary occlusion of the inferior and superior venae cavae and the azygos vein. Speed is imperative in this procedure, because survival can be assured only if the periods of occlusion are brief. The safety of the operation, which is considered too hazardous to be used in human patients, can be increased by modifications making it possible to fix the graft in place during a single brief period of venous obstruction. Insertion of the graft through a rubber-capped glass cylinder introduced into the base of the auricular appendage proved to be safe and free from the danger of air embolism or intracardiac thrombosis. The distance of the cylinder from the defect, however, made it difficult to place the sutures accurately. Improvements designed to overcome this and other difficulties are soon to be tested. Use of an invaginated pericardial pocket gave satisfactory results and seemed to fulfill the requirements of the ideal operation for use in human beings. Experience with one patient, however, showed that the pericardial pocket, when placed over a large defect, may be resorbed and literally melt away. Experiments now under way in which the technique is the same but an inert plastic material is used for the pocket will, if successful, provide a satisfactory method for the closure of atrial septal defects in human patients.

Pulmonary Valvuloplasty Using Mechanical Heart.—A mechanical heart was successfully used to bypass the right side of the heart completely during the operative correction of congenital pulmonary stenosis in a 16-year-old boy with longstanding exertional dyspnea. The left side of the heart and

the lungs continued to perform their functions, but the main pulmonary artery was clamped off for 25 minutes while the pulmonary valve was exposed and enlarged under direct vision. The blood flow through the mechanical heart was 4.5 liters per minute. The procedure was well tolerated, and the patient shows marked clinical improvement. He no longer complains of dyspnea and is working as a freight handler, although against advice. Partial bypassing of the right side of the heart with a blood flow of one liter per minute through a mechanical device was reported in 1952, but this is believed to be the first time the right side of the heart has been completely bypassed with success in a patient. The coexistence of septal defects would contraindicate this procedure in patients with pulmonary stenosis, but there are other conditions, such as disease of the tricuspid valves, in which it may prove useful. Blind valvulotomy has benefited many patients, but further progress in cardiac surgery will probably be based on exposure of the anatomic structures.

Influence of Potassium Salts on Parenteral Protein Alimentation.—Although potassium-nitrogen relationship in animals has been noted by several investigators, it was not until recently that Cannon and associates demonstrated the need for potassium salts in effective synthesis of tissue-protein in rats. The study presented here describes the enhancing effect of potassium salts on nitrogen utilization in human beings when adequate amounts of potassium are infused concurrently with high caloric protein hydrolysate. Studies were conducted on 10 men, patients of the Surgical Service, Wadsworth Hospital, Veterans Administration Center, Los Angeles, Calif. They were given no food by mouth for the experimental period. Electrolyte intake was recorded each day. Only the data on sodium, potassium, and nitrogen are considered here. Six different solutions were used. They were infused in combinations in amounts up to 4,000 cc. per day. The patients are divided

into four groups, according to the number of days treated and the solutions given. Evaluating observations on one patient from each group the authors stress the following points. 1. The efficiency of intravenous protein therapy is improved by the addition of potassium, since such a step replaces losses of electrolyte that occur with the destruction of cellular protoplasm during the fasting state. 2. There seems to be an intimate correlation between the rate of infusion, the presence of high caloric protein hydrolysate, and the amount of potassium required to replace these losses. 3. There is evidence that the amount of potassium needed per gram of nitrogen infused is intimately related to the improved retention and utilization of amino acids. This value has been found to exceed 5 mEq. per gram of nitrogen infused.

Arachnidism.—The black widow spider, *Latrodectus mactans*, has been reported in every state in this country except Vermont. It is especially prevalent in the southern states, the Ohio Valley, and the western coastal region. The name black widow originated from the fact that, after fertilization, the female kills the male. The adult female spider inflicts bites on humans. On the ventral surface of its abdomen is a characteristic hourglass (T-marking) red spot, and for this reason the black widow is known variously as hourglass, shoe-button, and T-spider. The venom of *Latrodectus mactans* is 15 times as potent as that of the rattlesnake. It is a thick translucent, oily, lemon-yellow-colored fluid, acid in reaction, from which a hemolysin and arachnolysin have been isolated. It is neither an alkaloid nor a glucoside but a toxalbumin. In a typical case of arachnidism, the history of having felt a bite or sting may be recalled only on questioning. The initial pain of the sting may be felt for only a few seconds or minutes. The onset of the next phase from 15 minutes to 2 hours later is heralded by the return of pain that spreads proximally and/or distally, following the lymphatic drainage. The predominant symptoms are excruciating and agonizing cramping pains of the abdomen; these equal or exceed those of ruptured peptic ulcer, kidney colic, acute appendicitis, or coronary occlusion. The muscle pain usually will involve almost all skeletal muscles. Other symptoms of arachnidism include convulsions, paralysis, urinary retention, shock, delirium, cyanosis, nausea, vomiting, dyspnea, anxiety, insomnia, and cold sweats. Observations by the authors in two cases of arachnidism are compared with reports by others. The results of the 80 or more treatments of arachnidism have been largely unsatisfactory. The best and only specific treatment is the antivenin *Latrodectus mactans*, which has been available for the past 12 years. This is an immune serum that has been prepared by concentrating and drying the serum of horses hyperimmunized with increasing doses of black widow spider venom. The dried antivenin is packaged with a 2.5 cc. vial of distilled water for restoring the serum and a 1 cc. vial of normal horse serum (diluted 1:10) as test and desensitizing material. It is imperative that instructions on the package be followed carefully, particularly in regard to the intradermal and conjunctival tests for hypersensitivity to horse serum. The usual dosage is 2.5 cc. of the restored serum, given deeply intramuscularly. A number of patients will require an additional 2.5 cc., which may be given one or two hours later.

Transorbital Lobotomy.—In a previous report the results of transorbital lobotomy in 200 state hospital patients were presented. This paper reviews findings in 400 patients. On the basis of interviews by several of the authors and reports from the ward nurses, the cases have been placed in one of five groups, out of the hospital, good improvement, fair improvement, no improvement, and operative death. There were 8 (2%) surgical deaths among the 400 patients. All of these patients had been considered hopeless and had failed to respond to all other types of therapy, including insulin and electroshock. The average duration of illness for the group is almost 11 years, and most of the patients had previously been confined to small seclusion rooms for years. The operation is quite simple and is well suited for use in a large state hospital. The operations are performed on the wards. A team of nurses and attendants can easily be trained in the course of two to four operations. Four operations take but 15 minutes. The patients are treated postoperatively as if they had had simple electroshock therapy. Morbidity is very low, and only a small percentage of patients are incontinent for a week or so. There have been two or three instances of transient hemiparesis. There was marked improvement in approximately one-half of the cases and some improvement in another 25% of chronically disturbed patients. It is urged that this type of operation be considered for all chronically disturbed patients.

Talc for Treatment of Recurrent Spontaneous Pneumothorax.—Recurrent and chronic spontaneous pneumothorax are dangerous. Prevention of further episodes in a person who has had several pneumothoraces is vital. The author presents observations on nine such patients who were treated with talc poudrage, both with and without concomitant resection. He shows that insufflation of sterile talc through a thoracoscope will glue the

visceral and parietal pleural surfaces together to prevent further pneumothoraces. The histories of five of the nine patients in whom this treatment was used are presented. Good results were obtained in eight of the nine.

Herpetic Stomatitis in Early Diagnosis of Infectious Mononucleosis.—Nathanson and Morin define both acute herpetic stomatitis and infectious mononucleosis and say that both have been attributed to a virus. They present observations on 52 cases of herpetic stomatitis, which were associated with a generalized lymphadenopathy leading to diagnosis of infectious mononucleosis. In 80% of the cases, the oral lesions preceded positive blood smear and agglutination tests. Thirty-seven patients sought dental consultation first. The presence of herpetic stomatitis in association with generalized lymphadenopathy is, in the opinion of these authors, consistent with the early diagnosis of infectious mononucleosis. A blood smear consistent with a diagnosis of infectious mononucleosis was present in all patients from the 5th to 20th day after presentation to the clinic. The oral lesions usually disappeared around the 10th to 15th day, although the blood smear may remain positive and the lymphadenopathy may persist for four weeks or longer. Treatment was directed to controlling the oral complaint. In addition to antipyretics and antibiotics for fever and infection, all patients were given vitamin B complex. The intramuscular and oral routes of administration were used alternately. In all cases the oral lesions improved, and the burning sensation began to disappear within 36 hours after start of therapy. The herpetic lesions began to regress within 48 hours, and tender gingivae showed distinct improvement within the same time interval. The response appeared to be better with the oral administration than with the intramuscular route. Administration of vitamins did not shorten the course of infectious mononucleosis.

Cerebrospinal Fluid in Man.—Sweet and Locksley point out that the textbooks teach that the cerebrospinal fluid is formed by the choroid plexuses of the cerebral ventricles whence it flows into the spinal and epicerebral subarachnoid spaces.

Here it is considered free to circulate until it is finally reabsorbed, presumably largely or wholly at the arachnoid villi. On the basis of data obtained from multiple simultaneous isotopic tracer studies in man, employing various combinations of Na^{24} , K^{42} , Cl^{38} , Br^{80} , P^{32} , HTO , D_2O , and radioiodinated human serum albumin, the authors were led to a unified theory of formation, flow, and reabsorption of the cerebrospinal fluid that is at variance with the currently held concepts. After a large number of tracer studies had been done in patients with normal cerebrospinal fluid systems, it became evident that a precise compartmental analysis of the data involved equations of a fair degree of complexity, and more variables than could be adequately measured, the most troublesome being the rate of flow between compartments. To limit the variables and to test the validity of a number of possible compartmental models of cerebrospinal fluid physiology, they sought patients in whom it would be possible to isolate the main ventricular compartments from the subarachnoid space. Two patients were found in whom complete blockage of cerebrospinal fluid outflow from the large lateral ventricles had resulted from tumor encroachment on the third ventricle. A normal state of cerebrospinal fluid pressure and dynamics was restored by means of a small plastic tube placed surgically to bypass the block and restore the flow of cerebrospinal fluid from the lateral ventricles to the basal cistern of the subarachnoid space. The authors stress the following points: 1. Water and electrolytes enter the cerebrospinal fluid rapidly both in the ventricles and throughout the subarachnoid space. The formation of the fluid is thus not an exclusive prerogative of the choroid plexus. 2. Water and electrolytes flow directly into the blood from both the ventricles and the subarachnoid space at roughly similar rates. 3. Cerebrospinal fluid does not suddenly come into being fully formed at any point with all its constituents in their proper ratios, but each constituent exchanges with blood at its own characteristic rate. 4. In contrast to water and electrolytes, protein is absorbed largely from the subarachnoid space, presumably from the arachnoid villi, which seem to function in the cerebrospinal fluid system analogous to the lymphatics of the general circulation. 5. The site and rate of protein reabsorption is an important determinant of the direction and rate of cerebrospinal fluid flow. 6. The net amount of cerebrospinal fluid elaborated per day in the ventricles, over and above the large and equivalent volume exchanged, is small and is of the order of 10 to 20 cc. or less, per day in man.

Isolation of Cocksackie Virus During Summer Outbreak of Acute Minor Illness.—The observations described were made as a part of a study of the epidemiology of poliomyelitis that is being conducted in Charleston, W. Va. In the last week of July, 1951, an unusual incidence of unclassified acute minor illness was noted in a block in one of the study areas in which households are regularly visited by interviewers. The block is adjacent to one from which a case of poliomyelitis had been reported earlier in the week. The situation was investigated to determine whether or not the two observations were related.

Stools and paired serum samples were collected and were frozen at about -20°C soon after collection and held at this temperature until tested. Neutralization tests were carried out on serums. The poliomyelitis patient was a boy, aged 6, who became ill with fever, drowsiness, nausea, and epigastric pain. A stiff neck developed the following day. A diagnosis of poliomyelitis was made two days later on the basis of increased lymphocytes in the spinal fluid, stiff neck, and hamstring muscle spasm. Weakness of abdominal muscles was noted on the following day and persisted for six weeks. The 1-year-old brother of this boy became ill three days later with fever and sore throat, and the pediatrician found small vesicles in the throat (herpangina). Several days later the mother had a sore throat. Six of 10 playmates (all less than 10 years old) of the 6-year-old boy with poliomyelitis also had sore throat and fever. Some had a syndrome compatible with herpangina. Both poliomyelitis virus and type A2 coxsackie virus were isolated from a fecal specimen from the boy with poliomyelitis, and a rise in neutralizing antibody titer to type A2 coxsackie virus was demonstrated. Stool specimens from household and playmate contacts with symptoms were found to contain type A2 coxsackie virus but not poliomyelitis virus. Adult members of the household possessed neutralizing antibodies to type A2 coxsackie virus, but none were found to be excreting virus.

Alcohol, Beer, and Wine as Foods.—According to Richter many Americans believe that alcohol needs food to dilute or absorb it and that the greater the amounts of imbibed alcohol the greater are the amounts of food that must be ingested. They regard alcohol as a drug and a "stimulant" that does not contribute directly to their diet. They do not consider that an ounce of alcohol represents almost twice as many calories as an ounce of sugar; nor have they considered the possibility that calories from imbibed alcohol added to those from ingested foods may supply far more energy than a person needs. Much of the experimental knowledge concerning the dietary needs of man is derived from observations on the Norway rat that has the ability to make beneficial dietary selections from wide assortments of foodstuffs. Its appetite has been amply demonstrated to be a reliable guide to its needs. The author described three series of experiments on rats. In one series the fluid consumption of rats was restricted to either an 8, 16 or 24% solution of alcohol for 265 days. The animals reduced their food intake in proportion to the calories obtained from alcohol. During this period they showed no signs of deficiency and gained weight at the same rate as before the experiment. In a second series of rats, the fluid intake was restricted to a table wine containing 12.5% alcohol by volume. The animals drank the wine, but in smaller amounts than tap water, and reduced their food intake in direct proportion to the calories obtained from the wine. In a third series, the fluid intake of rats was restricted to beer. The animals drank about twice as much beer during the experiment as water during the control period; they drank $2\frac{1}{2}$ to 3 times as much beer as animals in the second series of experiments drank wine. Food intake was reduced in direct proportion to the caloric volume of the ingested beer. Although the volume intake of beer greatly surpassed the intake of wine, the caloric intake was exactly the same, beer having a much lower number of

calories. While drinking either beer or wine, the rats gained weight at a normal rate and showed no dietary deficiency. These experiments confirmed that rats do not spontaneously consume more than a certain number of calories. The author believes that persons who drink alcohol should be made aware that they should eat less rather than more food when drinking alcoholic beverages and that food intake should be reduced in proportion to the caloric intake from the ingested alcohol.

Liver Disorders in Delirium Tremens.—Liver disease is an important and frequent complication of alcoholism. The present report is based on histological studies of the liver correlated with clinical and biochemical findings in 66 alcoholic patients with delirium tremens. The investigation was undertaken to further the evaluation of the incidence, cause reversibility, and sequels of hepatic abnormalities in alcoholism. The subjects were selected from a group of 338 admissions for alcoholism. There were 86 patients with delirium tremens, but 20 were excluded from the present study because of other complications. Each patient exhibited anxiety, hallucinations, delirium, and tremor. Sixty-one were men and five women. Their ages ranged from 28 to 72 years. Aspiration biopsy of the liver was performed with the Vim Silverman needle without complication. A diagnosis of normal liver was made when no significant cellular or structural changes were evident. The diagnosis of focal inflammation was based on the presence of small intralobular foci of lymphocytes or polymorphonuclear leukocytes without relation to the central vein. The diagnosis of fatty liver was made when intracellular and extracellular fat globules occupied 10% or more of the biopsy section. The diagnosis of portal cirrhosis was made in the presence of pseudolobulation, periportal fibrosis, and bile duct proliferation, with or without fatty or lymphocytic infiltration. A normal structure of the liver was found in 19, focal inflammation in 4, fatty infiltration in 20, and portal cirrhosis in 23 of the patients. Clinical and biochemical liver function studies did not provide a clue to the histological changes. The dissociation between biochemical tests and histology suggested that the latter was not responsible for the observed liver function changes. Hepatic abnormalities in delirium tremens appear to be due to dietary inadequacies. A diet deficient in lipotropic substances was associated with fatty infiltration and eventually led to fibrosis and portal cirrhosis. The degree of alcoholism and severity of cerebral symptoms could not be correlated with hepatic abnormalities. Rehabilitation of the alcoholic patient is desirable to prevent progressive liver injury. The fatty liver is curable, and prognosis in patients with hepatic fibrosis and portal cirrhosis is improved with treatment.

Irritable Colon.—Donovan says that terms like "spastic colon," "mucous colitis," "nervous diarrhea," and "unstable colon" have been applied to what he refers to as "irritable colon." This last term tends to focus attention mainly on colonic dysfunction, although small bowel and upper gastrointestinal irritability are often important. Because the gastrointestinal tract functions on a neuromuscular-glandular basis it easily becomes upset under emotional and irritative stimuli. In neuromuscular dysfunction there is either spasm or atony. Spasm can produce either constipation or diarrhea, but atony can produce only constipation. The spasm with associated dilatation proximal to the spasm will result in pain. The nausea, regurgitation, anorexia, and epigastric distress that accompany this motor disturbance reflect the additional component of small bowel irritability and pylorospasm that is frequently a part of the disease complex. The secretory disturbance is characterized particularly by the secretion of excessive amounts of mucus such as is seen in the so-called "mucous colitis." Most patients with the irritable colon syndrome have a combination of both motor and secretory dysfunction. The failure of physicians

to recognize the irritable colon as a functional bowel disorder constitutes one of the greatest single sources of error in the diagnosis and treatment of the patient with abdominal pain. This is proved by the large numbers of patients who have been subjected to needless surgical operations for adhesions, appendicitis, biliary tract disease, stomach and duodenal disorders, and on the pelvic organs, and who nevertheless continue to complain of the same symptoms. The differential diagnosis of irritable colon must be made by exclusion. X-ray study serves to exclude an organic disease. Both physical and mental rest for the patient and rest for the colon are the keystones of treatment. Giving the patient an explanation of normal colonic physiology in simple easily understood terms and explaining how an alteration in this coordinated mechanism accounts for his symptoms is also of great therapeutic value. Rest for the colon begins with breaking down of excessive bowel consciousness. The use of all cathartics, colonic irrigations, and enemas must be stopped, and this is most easily accomplished by an explanation of their harmful effects and how they interfere with normal reflexes. A low residue diet is used at the beginning in patients with irritability. The diet may be gradually changed to one containing natural bulk foods, such as vegetables, whole grain bread and cereals, and salads, when the irritable stage has subsided. Fruits and vegetables may be added early if they are cooked, but they should not be eaten raw until later. Adequate amounts of fluids should be prescribed. Sedatives and antispasmodics play a part in treatment of excessive emotional and parasympathetic stimuli.

Mass Treatment of Endamoeba Histolytica Carriers.—It is generally believed that about 10% of the Japanese people harbor *Endamoeba histolytica*. Most persons with such infections are asymptomatic, and the question has been raised as to

the value of treating them. In two villages in Japan, 241 persons were selected for treatment. Diagnosis was based on five fecal examinations (formaldehyde-ether concentration technique) per person. Carbarsone was administered the first week and chiniofon the second week. Every three days the patients were interviewed and their symptoms and side-reactions to the drug, if any, noted. Five weeks and again seven months after treatment, each patient had five stool examinations. Of 124 patients infected with *E. histolytica*, 18 were excluded either because of inadequate therapy or incomplete follow-up. Of the remaining 106, only one was still infected five weeks after treatment. A survey seven months after treatment showed four (3.8%) with *E. histolytica*. Ultimate benefits from mass treatment will depend on how quickly reinfections occur.

Cancer and Parental Age.—It has been maintained that the great increase in cancer mortality at the present time is due in part to the increased average expectancy of life in man. It becomes necessary, therefore, to resolve the problems of the expectancy of life and of cancer susceptibility into their component parts. Investigators have shown in experimental animals that maternal age influences cancer susceptibility in the offspring. These are Bittner working with adenocarcinoma of the mammary gland, MacDowell and Law investigating leukemia, and Strong studying chemically induced fibrosarcoma. These studies have all been done on mice. The experimental work on chemically induced fibrosarcomas in mice has shown that the ordinal sequence of litters influences fibrosarcoma susceptibility, obviously a reflection of maternal, if not parental, age and that the size of the family determines trends in cancer susceptibility. Studies on the life expectancy in man have been reported by a number of investigators who proved that longevity in man is influenced by (1) maternal age at the time the child was born, (2) the number of children in the family, (3) the decrease of infant mortality with advancing age of parents, (4) the age at death of the parents, and probably by many other factors. It is proposed now by investigators representing the various biological fields, such as genetics, gerontology, medicine, public health, etc., to pursue the following program on human subjects; (1) ascertain data on parental (particularly maternal) age at birth of cancer proband and to compare these data with a similar group of controls (noncancer) of approximately the same age and circumstances; (2) determine the ordinal sequence of the family for cancer patients and their controls; and (3) ascertain data on vital statistics for older and younger brothers and sisters to cancer patients and their controls. This preliminary program should indicate (1) where cancer has occurred in a large family, (2) the most likely types of human cancer that should be more carefully investigated, (3) the causes of death of brothers and sisters of cancer patients and their controls, and (4) whether the differences in cancer susceptibility between children of subsequent births are great enough to warrant a more extended investigation over a period of years of the possible cumulative effect of maternal age or restriction of the size of the family on cancer in the human offspring.

Diagnosis of Bronchogenic Carcinoma.—Diagnosis and evaluation of chances of surgical intervention are discussed on the basis of 329 patients with cancer of the lung, most of whom were admitted to the Department of Thoracic Surgery, Rigshospitalet, Copenhagen, between 1943 and 1949, while a few were admitted in the course of the last three years. Eighty-eight, 26.7%, underwent a pneumonectomy or lobectomy and in 241 the condition was considered inoperable. Of the pathological changes revealed by radiography, atelectasis occurring in 209 patients (63.5%) was the commonest; next in frequency was neoplastic infiltration that was observed in 149 patients (45.3%). The operability in the presence of atelectasis and neoplastic infiltration corresponded to the average number of patients operated on, as contrasted with the fact that in 89 patients (27.1%) with a hilar shadow only 12 lesions (13.5%) were operable. The operability was significantly higher in patients with an isolated round tumor plus isolated cysts and abscesses than in the remainder of the series. In searching for a tumor of the lung the anteroposterior exposure must always be supplemented by a lateral one. In 130 of the 241 inoperable cases and in 50 of the 88 operable cases, the tumor was visible on bronchoscopy. The great significance of bronchoscopy is stressed. Bronchography may be of value in diagnosis and of decisive significance in some cases, particularly when bronchoscopic examination showed a normal appearance. Obstruction of a bronchus by the tumor was revealed in 65 of 68 inoperable cases with positive bronchographic findings, but occasionally apparent obstruction of the bronchus is not caused by a tumor, but by accumulation of secretion or granulation tissue. Tomography is an adjunct to bronchography in revealing possible obstruction of bronchi by a tumor, but a certain reserve in interpreting the shadow is advisable. Cytological examination of the sputum was of limited value. Enlargement of the mediastinal lymph nodes demonstrated by tomography and bronchoscopy (and bronchography) is a serious sign, but in a large number of patients it was possible to perform radical extirpation of lymph nodes, and, in almost 50% of those studied microscopically, the removed lymph nodes did not contain metastases. Extensive use of exploratory thoracotomy is necessary; even at operation it may be difficult occasionally to determine the nature of the lesion. Microscopic examination of frozen sections of a biopsy specimen is of great importance and should be done in all doubtful cases. The value of this procedure is, however, also limited since in cases of centrally located small tumors the biopsy specimen is often obtained from the peripheral area and shows only atelectasis and inflammation. Only positive biopsy findings are reliable. In the absence of a biopsy specimen, the result of one of the other diagnostic methods should not be considered decisive, but the findings from all of them should be combined to give a final result.

Serologic Findings in Infants Given Exchange Transfusions.—The behavior of the Coombs' test, of the antibody titer, and of the Rh-positive blood corpuscles was studied in the course of exchange transfusions given to 31 infants with erythroblastosis

fetalis. Specimens of the infants' blood were drawn before the start of the transfusion and each time after the administration of 100 cc. of blood. The exchange transfusions were given according to Diamond's technique. The amount of the exchanged blood varied from 500 to 900 cc. All the infants had positive results from the Coombs' test before the start of the transfusion, but conversion to negative occurred in all except two. In most of them the change occurred after an exchange of only 300 to 400 cc., although Rh-positive blood corpuscles, free antibodies, and free antibodies and Rh-positive blood corpuscles could still be demonstrated in the blood specimens. After an exchange of 500 cc. of blood, Rh-positive blood corpuscles and/or free antibodies were still observed in seven infants (21%) and after an exchange of 600 cc. in four infants (12%). The remaining Rh-positive blood corpuscles, the persistent antibodies, and the bilirubin originating from the hemolysis of the blood corpuscles may exert an injurious influence on the tissue. The aim of the therapy must, therefore, be to reduce these substances to a minimum. Diamond's and Wiener's better results obtained with larger transfusion amounts may be attributed to further reduction of antibodies and bilirubin in the infant, an assumption that should be confirmed by special studies. These better results and Zwirn's serologic findings in the course of the exchange transfusions in the 31 infants show the inadequacy of giving less than 700 cc. of blood. The author recommends an exchange of 750 to 1,000 cc. of blood in the course of the first exchange transfusion without excluding the occasional use of repeated transfusions.

 Treatment of Acute Experimental Renal Insufficiency with Intestinal Perfusion Through an Appendicostomy. T. F. Lago.—p. 473.

Nutrition of Arterial Grafts.—The authors' experimental studies on the source of nutrition of arterial grafts indicated that the first nourishment comes from the perivascular tissues of the host and that later there is an ingrowth of connective tissue elements into the coats of the graft with the formation of new vessels. It was also revealed that contact of the graft with the surrounding tissues is indispensable not only for the nutrition of the graft but also for a successful anastomosis. There was always degeneration, fragmentation, and necrosis of the connective tissue and muscle fibers of the graft when it was isolated from the surrounding tissue by means of polyethylene sheets. These changes began in the outer coat progressing to the inner coat and causing formation of a thrombus in the lumen of the graft. Necrotic alterations were not observed when the arterial segment was isolated from all contact other than the surrounding tissue. When the blood stream was diverted from the graft, there were at first degenerative changes in the inner coats with deterioration of the intima and media; but these were rapidly restored to normal by elements of the connective tissue of the host thus suggesting that some connections had been formed between the outer coat of the graft and the surrounding tissue and that nutrition was arriving from it to the inner coat of the graft. In cases in which the graft was in contact with the blood stream only, the outer coat began to deteriorate rapidly; later the degenerative process involved the media and the intima that had at first remained unaltered and maintained their vital aspects. The authors conclude that the source of nutrition of arterial grafts is dual, the blood stream pulsating through the graft and the surrounding tissues. Since the latter is indispensable, it is important that the arterial graft be surrounded by as much vascular tissue as possible to promote vascularization of the graft.

Vital Activity in Arterial Grafts.—Studies were made to determine whether there is in the walls of arterial grafts some of the vital activity that is present in the walls of arteries in normal conditions. The possibility of the presence of a granulopoietic activity was tested by introducing small amounts of diluted China ink into the walls of the grafts and, for control, into the walls of the stumps of the host artery and of normal arteries. The histo-

logical studies, made from the 3rd to the 40th day after the graft was performed, indicated that from the first days large cells filled with granules of ink were present in the walls of the grafts. They were located mainly around the area into which the ink had been injected and became numerous with time. Later greater quantities of granules assembled in the perivascular connective tissue. The same phenomenon was observed in identical quantitative and chronological order in the walls of the arterial stumps and the normal arteries. Ink was also fixed when the walls of normal arteries were isolated from the surrounding tissue by means of polyethylene sheets. But there was no sign of granulopoietic activity in the walls of grafted arterial segments when they were likewise isolated. According to the authors, these histiocyte-like elements that are autochthonous in normal arteries are also present in the arterial grafts at the time of the operation, but they have lost their ability to fix China ink because of a state of functional inhibition. Their state is similar to what Carrel called a state of "latent life." They attributed the presence of the granulopoietic activity in the walls of the normally grafted arterial segments to the fact that histiocyte-like elements with this activity had migrated into the wall of the graft from the surrounding tissues.

The Endocrine Factor in Disturbances of Adaptation in the Nursing. F. C. Millia.—p. 79.

Hemispherectomy in Infantile Hemiplegia.—Organic cerebral lesions sustained during pregnancy, birth, or early infancy may be followed by infantile hemiplegia. The onset, which is usually more or less abrupt, is succeeded by a period of limited recovery, after which the condition becomes stabilized. The resulting atrophic lesion, with its accompanying gliosis and neuron destruction, may be either localized or diffuse, sometimes even extending throughout the hemisphere. Paralysis is generally less pronounced than in the adult, but character changes and a diminution in intellectual capacity, ranging from moderate oligophrenia to idiocy, are frequent, and many of the patients suffer epileptic attacks of varying severity. The mental disturbances to which they are subject are probably due in large part to the epileptogenic activity of the affected hemisphere. Hemispherectomy, which has proved effective in arresting epilepsy and checking progressive mental deterioration in patients in whom epileptic manifestations are associated with hemiplegia, was used successfully by the author in four children ranging in age from 6 to 9 years. The patients are still handicapped by their intellectual deficit and hemiparesis, but the benefits derived from the elimination of epileptic attacks and the improvement in their conduct are inestimable. Removal of the diseased hemisphere has apparently been followed by better utilization of the healthy one.

Pancreatitis.—The clinical features and laboratory investigations in 24 proved cases of acute and chronic pancreatitis were studied at the Royal Melbourne Hospital in Melbourne, Australia. It is felt that the confusion of thought that exists on this subject might in part be dispelled if attention were paid to the etiological aspects of the problem. The authors differentiate five clinical entities—traumatic pancreatitis following surgery of the stomach and duodenum; virus pancreatitis complicating mumps and possibly infectious hepatitis; reflux pancreatitis complicating biliary

calculi and following cholecystectomy; chronic nutritional pancreatitis or "chronic relapsing pancreatitis," in malnourished alcoholic patients; and metabolic pancreatitis complicating hyperlipemia and hypercholesterolemia. In acute pancreatic necrosis, good results were obtained with conservative treatment—continuous aspiration of the gastric contents, electrolyte replacement, and administration of antibiotics. Chronic relapsing, or nutritional, pancreatitis is a condition characterized by recurrent attacks of pancreatic edema and necrosis causing pain; ultimately, destruction of the gland and replacement fibrosis lead to wasting, steatorrhea, and diabetes. Pancreatic calcification is occasionally visible radiologically and induration of the head of the pancreas may cause obstructive jaundice. In the absence of biliary calculi, cholecystectomy is contraindicated in chronic pancreatitis. When severe and unremitting pain becomes a feature in advanced cases, a choice must be made between sympathectomy and pancreaticoduodenectomy. Relapsing "reflux" pancreatitis was found to occur in female patients after cholecystectomy. Further data on the mechanics of the sphincter of Oddi and the common bile duct are required before agreement on the surgical relief of these patients can be reached. The diagnosis of mild cases of acute and chronic pancreatitis may be difficult. Although elevation of the urinary diastase level is helpful, this may be only transient. Collateral evidence of steatorrhea, glycosuria, pancreatic calcification, and impaired protein digestion should be sought for in diagnosing chronic pancreatitis of all types.

I-Noradrenaline in Cardiogenic Shock.—Pressor substances such as epinephrine (Adrenalin) and ephedrine have not been used in the past in the treatment of severe, persistent cardiogenic shock because of the risk of inducing ventricular fibrillation. Arterenol (Noradrenaline) and, particularly I-arterenol (I-Noradrenaline) do not present the same disadvantages, and it is their successful use in anesthesiology that prompted this experiment. Six patients in severe shock owing to cardiac infarction were treated by intravenous infusions of dextrose-saline containing levarterenol bitartrate (Levophed). In all of them death appeared imminent or probable; the systolic blood pressure had fallen to levels between 45 and 80, and in two instances the wrist pulse could not be felt. In each case, the start of the infusion was followed at once by clinical improvement; the systolic pressure rose to levels between 90 and 100, and the pulse became palpable. Where consciousness had been lost it was regained. Two patients who had had previous infarcts responded in this way to the infusion, but died within three and four days; recent as well as old infarctions were proved at necropsy. The remaining four patients made good recoveries after discontinuance of the infusions. One died of congestive heart failure four months after the cardiac infarction; but the other three were alive and active at intervals ranging from six to 13 months afterwards. Their lives apparently were saved by the treatment.

Synergistic Effect of Penicillin and Streptomycin in Peritonitis.—Penicillin combined with streptomycin was given intraperitoneally to 54 patients with perforative peritonitis. Of the 54 patients, 20 had perforating gastric and duodenal ulcers, 6 had perforating gallbladders, 16 had progressive peritonitis after perforative appendicitis, and 12 had diffuse peritonitis after perforative appendicitis. Most of the patients were operated on on the second to the fourth day of the disease. The dose of the intraperitoneally administered drugs depended on the severity of the patient's condition. Those with progressive and particularly with diffuse peritonitis were given 200,000 to 1,000,000 units of penicillin and 1 to 2 gm. of streptomycin. Combined administration of penicillin and streptomycin frequently was repeated with the aid of an intraperitoneal drain on the first two to three postoperative

days. Intraperitoneal administration of the antibiotics is of great importance because defense processes of the organism against the pathogenic agents that have entered the free abdominal cavity take place directly in the abdominal cavity and not in the blood stream. To prevent a rapid lowering of the concentration of the drugs in the abdominal cavity, additional intramuscular injections of 200,000 units of repository penicillin and of 0.5 gm. of streptomycin were given every 12 hours. The total dose of the parenterally administered drugs was 2 to 3,000,000 units of penicillin and 4 to 6 gm. of streptomycin. The antibiotics were given in solution, i. e., 200,000 units of penicillin in 2 cc. of isotonic sodium chloride solution and 1 gm. of dihydrostreptomycin in 4 cc. of the same solution. Death from diffuse peritonitis did not occur, not even in desperately ill patients. The deaths of two patients resulted from different causes; one 75-year-old man with perforating gallbladder died of suppurative bronchopneumonia on the sixth postoperative day, and one 65-year-old man died of pulmonary embolism on the 11th day after suture of a perforating duodenal ulcer. Penicillin combined with streptomycin exerted a synergistic effect on the mixed bacterial flora comprised of coli bacteria, streptococci, enterococci, *Clostridium perfringens*, and anaerobic micrococci, with striking improvement of the patient's condition. Paralytic ileus occurred only sporadically. Toxinemia, which occurred shortly after the intraperitoneal administration of the antibiotics, presented a difficult problem, but administration of antihistaminic agents and a proprietary keratin derivative (Detoxin) proved effective in its control. The intraperitoneal administration of the antibiotics did not impair the peristalsis, and there was no evidence of formation of adhesions.

Utilization of Folic Acid in Anemia and Leukemia.—Spray and Wits include under the term folic acid all substances in plasma and urine that stimulate the growth of *Lactobacillus casei* in microbiological assays; the term pteroyl glutamic acid is used to refer only to the pure compound. The authors had observed previously that, after doses of 1 mg. of pteroyl glutamic acid by mouth, untreated patients with pernicious anemia and with steatorrhea showed lower concentrations of folic acid in the plasma, and lower urinary excretion of the vitamin, than either normal persons or patients with pernicious anemia in remission. This suggested either that there was deficient absorption of folic acid in pernicious anemia or, more probably, that there was an abnormal demand for folic acid associated with shortage of the other hemopoietic factor, vitamin B₁₂. In the hope of obtaining further information about the role of folic acid in hemopoiesis, the concentrations of folic acid in the plasma and its excretion in the urine were measured before and after the oral administration of 1 mg. of pteroyl glutamic acid in a series of patients with a variety of anemic and leukemic conditions. The series here reported includes eight patients with hypochromic anemia before treatment, two with hypochromic anemia under treatment, one with scurvy, two with pernicious anemia under treatment with vitamin B₁₂, and eight with hemolytic anemia. Data are also given on one patient with polycythemia vera and nine patients with chronic myeloid or chronic lymphatic leukemia. The results were compared with the responses of normal persons to the same test. There appears to be normal utilization of folic acid in hypochromic anemia both before and during treatment, but the patient with scurvy and the two patients with pernicious anemia under treatment with vitamin B₁₂ all showed abnormally low levels of

folic acid in the plasma and low excretion in the urine. In hemolytic anemia there is a slight indication of an increased demand for folic acid, as shown by lower levels of folic acid in the plasma and somewhat lower urinary excretion than in normal persons after a test dose. The single patient with polycythemia vera responded to the test normally, but most of the patients with leukemia showed low levels of folic acid in plasma and urine. The authors feel that these observations support the idea that folic acid and vitamin B₁₂ are both involved in the synthesis of the same constituents of the red blood cell, perhaps nucleoproteins, and only when there is a shortage of some substance involved in this particular chain of reactions does an abnormal demand for folic acid appear. Folic acid also apparently plays some part in the formation of white blood cells, but its role in this respect is even less clear than its role in erythropoiesis.

Roentgenologic Aspects of Pulmonary Changes in Poliomyelitis.

—The pulmonary complications often have a decisive influence on the course of respiratory paralysis in poliomyelitis. For this reason Volbeding and Repkewitz employed all diagnostic resources to detect such pulmonary complications early. In addition to the customary clinical, chemical, and neurological methods of examination, they resorted to roentgenoscopy, although it involves considerable technical difficulties, particularly if patients are paralyzed and/or confined in an iron lung. Their studies were made in a Hamburg hospital to which 226 of a total of 446 patients with poliomyelitis were admitted during the Hamburg poliomyelitis epidemic of 1947. During the years 1948, 1949, and 1950, the patients admitted to this same hospital numbered 98, 27, and 17, respectively, or a total of 368 in the course of the four years. A table records among other data the number of patients in whom roentgenoscopy was done and the various complications that were detected. There was a considerable number of adults with poliomyelitis who had massive atelectasis. In discussing the pathogenesis of this form of atelectasis, the authors suggest that profuse formation of mucus in the upper respiratory tract, because of paralysis of the muscles of inspiration, is probably the chief cause. This profuse formation of mucus may even bring about obstruction of bronchi as was revealed by bronchoscopic examinations carried out by American investigators. Bronchopneumonia usually occurred during the final stage. Diaphragmatic paralysis of various degrees of severity were also detected by roentgenoscopy. Atrophied intercostal muscles likewise presented characteristic features on the chest roentgenograms.

*Vertigo in Random Sample of Elderly People Living in Their Homes. H. Droller and J. Pemberton.—p. 689.

Vertigo in Elderly Persons.—According to Droller and Pemberton, vertigo, often referred to as dizziness or giddiness, is the sensation of apparent movement. This movement may be in any direction and is not necessarily rotatory. It is always associated with difficulty in maintaining balance and makes the sufferer clutch for support. The observations reported are based on the medical examinations of 476 elderly persons of Sheffield, living in their own homes, either alone or with their spouses. Information on the incidence and degree of severity of vertigo was systematically collected for the whole group. Data for blood pressure at rest and after two minutes standing and data on tinnitus and deafness were also collected. The incidence of vertigo was 47% in the men and 61% in the women. In the majority vertigo appeared to be closely associated with arteriosclerosis of the labyrinth. In a small number of subjects a drop in blood pressure on changing from the supine to the upright position brought on an attack. Typical Ménière's syndrome was rare. In a few subjects several vertigo-producing factors operated simultaneously.

Neuromuscular Transmission in Myasthenia Gravis.—According to Churchill-Davidson and Richardson it is generally accepted that the functional abnormality in myasthenia gravis is a failure of neuromuscular transmission, and the previous theories of causation have been derived from studies of the action of acetylcholine in normal neuromuscular transmission. The introduction of decamethonium salts that act in a manner similar to acetylcholine has allowed a reinvestigation of the mechanism of not only normal but also myasthenic neuromuscular transmission and, in particular, has indicated the response of the motor end-plates in these states to chemical excitation. In this study the reaction of myasthenic muscles to decamethonium is contrasted with that of normal muscles under identical conditions and the mechanism of these different reactions investigated. It was found that if sufficiently high doses of decamethonium are given to patients with myasthenia gravis, the muscles that show the greatest degree of clinical weakness are the first to undergo a failure of neuromuscular transmission. The neuromuscular block, when produced, has the characteristics of one due to competitive inhibition. The clinically normal muscles of myasthenics possess a marked tolerance to the depolarizing action of decamethonium iodide. A comparison of the urinary excretion of decamethonium in myasthenic patients and normal subjects indicates that there is no significant difference in the two groups. The fact that decamethonium is excreted by myasthenics unchanged indicates that the ultimate production of competitive inhibition in myasthenia by decamethonium is in fact due to changes in the motor end-plate. The authors suggest that the failure of neuromuscular transmission in myasthenia is derived from abnormalities in the response of the motor end-plate to acetylcholine.

Liver Changes in Schistosomiasis in Children: (Preliminary Report). E. Stransky and N. E. Pesigan.—p. 261.

Sickle Cell Disease in Jamaica.—While the sickle cell trait is found in only from 5 to 10% of American Negroes, the incidence of sickle cell anemias is relatively high. In contrast to this, in tropical Africa, it is usually conceded that the opposite is true—the trait being much more frequent and the anemia surprisingly uncommon. The population of Jamaica is mixed. The 1943 census showed that, of the 1,237,063 inhabitants, the main racial groups were made up as follows: (1) predominantly African, 78.1%; (2) other Afro-Caucasian or Afro-Asian mixtures, 17.5%; (3) Caucasian, 1.1%; (4) East Indian, 2.1%; and (5) Chinese, 1%. In a recent sickle cell survey by Jelliffe and others, 2,116 Jamaican children of different racial groups were tested. Chinese, East Indian, and Caucasian subjects showed no sickling, while, of the main group of mixed Afro-Caucasian descent, 5.7% were found to have the sickle cell trait. This is in accord with results obtained with similar groups elsewhere in the Caribbean, as for example 5.3% in Cuba, 5.6% in Puerto Rico, 5.5% in Martinique, 8% in Guadeloupe, and 11.7% in Curaçao. The commonness of sickle cell anemia among Negroes in the Americas and the Caribbean has sometimes been explained by the better facilities available for diagnosis, together with the possibility that patients are more likely to attend for treatment in these areas. While this is certainly a partial explanation, it is the author's experience that the difference is a real one. In Ibadan, a large African city of half a million persons in western Nigeria, 23.7% have been shown to be trait carriers, while only 22 cases of sickle cell anemia were seen in an 18 month period. In contrast to this, the much lower trait incidence in Jamaica of 5.7% and the commonness of the anemic state are striking. The reason for this apparent paradox is still unknown. It has been suggested, however, that the commonness of sickle cell anemia in the New World as opposed to Africa was due to the admixture of African and Caucasian genes as a result of intermarriage. Recent genetic and clinical studies, summarized by Zuelzer in 1952, may possibly partially confirm this concept.

begin either as a frank tuberculoid or lepromatous form. Polyneuritic lesions, whether alone or complicated by the main types, are considerably less frequent in these countries. Although leprosy may be evanescent in childhood, the author believes that in a great proportion of the children leprosy would progress and cause infection of others. There is a lack of adequate accommodation in these countries for all existing cases of leprosy, but special attention to children is recommended as one of the most economic and fruitful forms of attack on the leprosy problem.

 Penicillin Sensitivity. P. W. Farmer.—p. 820.

Fertility and Sterility After Ectopic Pregnancy.—It is commonly believed that the occurrence of an ectopic gestation will in no way prejudice a woman's chances of producing a living child later on. In order to answer several questions on the relationship between ectopic pregnancy and sterility, Grant made studies on 259 women who had had ectopic pregnancy and who had been observed at two different departments of a Sydney women's hospital. The studies on these women and reports in the literature clearly show that the occurrence of an ectopic pregnancy is a major accident for the patient who wishes to produce a family, because, at the best estimate, only one-third of such patients will ever succeed in having a live baby, and in many groups the obstetric prognosis is much worse. Some investigators found that only one in every six of such women had a live baby during the rest of their life. Inquiry into the causes of this sterility reveals that it is located in the Fallopian tubes in 67% of the cases reviewed here and that most likely the tubal factor is involved in 81% of the cases. The incidence of ectopic gestation in patients attending a sterility clinic is seven times the usual incidence, and the frequency of ectopic gestation in patients treated for tubal blockage by high-pressure insufflation is 25 times that found among other pregnant women. The alternatives are to do nothing or to operate. However, tubal plastic operations are not yet very successful. The damage to the residual tube in most of the patients who have had an ectopic pregnancy appears to have been the result of salpingectomy in 50% of cases. The other 50% suffered bilateral tubal damage at the time of the original septic lesion in the pelvis, which preceded the occurrence of the ectopic gestation. No patient has been adequately treated for an ectopic pregnancy until her one residual tube has been proved patent by subsequent insufflation with carbon dioxide or by salpingography with the use of an aqueous and nonirritating medium.

- Leprosy in Anglo-Egyptian Sudan East and Central Africa. R. G. Cochran.—p. 177.
 *The Leprotic Child in Africa. J. R. Innes.—p. 224.

The Child with Leprosy in Africa.—Innes carried out leprosy surveys in East Africa from 1946 to 1951. Most of the data obtained were reported previously. This paper is concerned with 1,492 cases of leprosy in children which were found in the natural or untreated state in a total of 7,072 cases of leprosy of all ages. The term child is used to include all persons of 14 years of age and under. The countries in which these 1,492 cases in children were found comprise Kenya, Tanganyika, Zanzibar and Pemba, Uganda, northern Rhodesia, and Nyasaland. Nearly every African tribe resident in these countries is represented in these children who were not in leprosariums but who came from the homes and villages and who at the time of discovery were living in the same conditions as their siblings who did not have leprosy. The fact that children accounted for 21% of all cases of leprosy indicates that leprosy is a living and continuing entity among these peoples. The sex ratio was 4:3, with males predominating. Analysis of the ages indicated a great increase between 5 and 14, which suggests that many must have sustained their infection at an early age. There were no indications that leprosy was acquired by one or a few momentary contacts, but rather by living in daily, and more especially nightly, contact with persons with leprosy in the family group. Leprosy in children and the young is mainly a problem of environment and living conditions. Protection of children from leprosy is an important key to the eradication of leprosy from a community. Leprosy in children

of the 17-ketosteroids in 17 women in whom interventions for gynecologic disorders had been performed at the Novara school of obstetrics. A marked eosinopenia, which was paralleled by an increased ratio between uric acid and creatinine, was found immediately after the operation in most of the patients; the changes in the 17-ketosteroids were not so marked and constant, but their excretion was slightly increased. These alterations are ascribed to an alarm phase of the general adaptation syndrome of Selye. The surgical trauma, which stimulates the adrenal cortex to a degree proportional to its length rather than its gravity, determines a greater peripheral need for corticoids, the blood level of which is, therefore, decreased; the hypophysis reacts by elaborating a greater amount of corticotropin; and this in turn stimulates the adrenal to a greater production of corticoids. When the stress ceases, the hyperactivity of the hypophyseal-adrenal system decreases and these blood and urine tests are again normal. In the authors' patients the eosinophils increased to above the preoperative values only by the eighth day, whereas the acid uric-creatinine ratio had already become normal by the 24th or 48th hour. Complications of the postoperative course delayed this return to normal. The authors conclude that the presence of a marked eosinopenia and an increased ratio between acid uric and creatinine within the first 24 postoperative hours suggest that the function of the patient's hypophyseal-adrenal system is good and the neuroendocrine defense reaction to the intervention will be efficient. An immediate postoperative marked eosinopenia is sufficient to eliminate the hypothesis of corticoadrenal deficiency in cases of shock. On the other hand, an increased number of eosinophils and irrelevant changes in the acid uric-creatinine ratio immediately after the intervention suggest adrenal insufficiency and possibly a bad prognosis. Of prognostic value is also a premature or a late return of these blood and urine alterations to the preoperative values. These blood and urine determinations have postoperatively the same prognostic value that Thorn's test with corticotropin has preoperatively.

Presse Médicale, Paris

- *Dosage of Isoniazid (Isonicotinic Acid Hydrazide) in Children. R.-A. Marquézy, C. Bach and J.-P. Clermont.—p. 1569.
- Remarks on Antineoplastic Function of Certain Adrenal Hormones. A. Josseland.—p. 1571.
- *Value of Comparative Study of Serial Electroencephalograms in Etiologic Diagnosis of Various Cerebral Afflictions. S. Thiry.—p. 1572.

Dosage of Isoniazid in Children.—The authors were impressed by the innocuousness of large doses of isoniazid in children. Eighty-four children hospitalized for tuberculous meningitis or simple primary infection) were treated with large doses of isoniazid (40 times between 20 and 30 mg. per kilogram of body weight, and 11 times between 30 and 40 mg. per kilogram of body weight); this treatment lasted for from two to seven months. Clinical tolerance was remarkable, and biological examinations revealed almost no evidence of renal or hepatic involvement, with the exception of six cases of mild disturbance in galactose clearance. These strong doses enable high concentrations of isoniazid to be achieved in the blood. The blood concentration of isoniazid of 2 or 3 mcg. per cubic centimeter for the classic daily dose of 10 mg. per kilogram is raised to 6 to 10 mcg. per cubic centimeter for a daily dose of 20 to 30 mg. per kilogram and vacillates between 10 and 25 mcg. for a daily dose of 40 mg. per kilogram. These elevated doses, which are well tolerated by children, seem to be very useful in serious cases, since only the blood concentrations thus obtained are capable of acting on strains of bacilli that are most resistant.

Serial Electroencephalograms.—The author describes three cases in each of which a study of electroencephalograms taken at intervals of a few days during the course of illness was the decisive factor in establishing a diagnosis of cerebral tumor (in two cases) or of cerebrovascular accident (in one case). This method was previously used by him in the study of cerebral thrombophlebitis, the differential diagnosis of thrombophlebitis and cerebral abscess, and the progressive localization of a diffuent cerebral abscess. It is emphasized that this study of consecutive electroencephalograms must be analyzed

in the light of other clinical findings and information about the patient; on the other hand, electroencephalography is a simple and harmless procedure that has great value in early diagnosis. In these three cases, cerebral arteriography and ventriculography showed no abnormalities, but the diagnoses made on the basis of the electroencephalograms were confirmed at operation in the case of the two cerebral tumors and by response to treatment with vasodilators, anticoagulants, and short waves in the case of the vascular disturbance.

- *Prevention of Operative Shock by Methonium Compounds in Visceral Surgery: Based on 120 Cases. Du Callar.—p. 1595.

Methonium in Prevention of Operative Shock.—The author's technique is described for the use of controlled hypotension with one of the methonium derivatives in patients undergoing various surgical operations of the viscera. He used the substance pentamethonium bromide (C-5) in conjunction with other neuroplegics—Diparcol (10-[2-diethylaminoethyl]-phenothiazine), procaine, and Phenergan (10-[2-dimethylamino-1-propyl] phenothiazine)—in order to achieve a polyvalent neurovegetative stabilization through multifocal neurovegetative blocking that is effective both centrally and peripherally. This stability is necessary as a supplementary aid to the methonium in blocking the severe reflex to splanchnic irritation. The 120 patients on whom these observations are based had had hysterectomies, gastrectomies, abdominoperineal amputations of the rectum, endothoracic surgery of the lung, esophagus, and heart, and peripheral operations of the face, neck, breast, etc. Vasoplegia and hypotension were moderate when this method was used; the spare in blood loss was evaluated as two-thirds. No postoperative shock was observed in any case, and it is felt that this method of using methonium derivatives yields a significant antishock effect.

Digestive Disorders from Phenylbutazone.—The authors personally saw three patients in whom severe digestive reactions developed subsequent to the administration of phenylbutazone (Butazolidin) as an antirheumatic. In the first patient, there was reactivation of an old duodenal ulcer with hemorrhages; in the second, epigastric pain, severe alimentary vomiting, melena, and hematemesis; and in the third, transient edema of the lower extremities, severe epigastric pain, and probable reactivation of a duodenal ulcer. These cases are consistent with those reported in the literature, and review of them all establishes that phenylbutazone can cause simple reactivation of an ulcer, digestive hemorrhages, digestive perforations, bouts of ulcerous activity representing the evolution of multiple ulcers, and probably even new ulcers. In view of the remarkable similarity between digestive disorders caused by phenylbutazone and those caused by cortisone and corticotropin, the authors feel that the hypothetical mechanism of disturbances following hormone therapy should be kept in mind, namely hypersecretion of hydrochloric acid in the stomach due to adrenocortical stimulation. Of all the other disturbances that

Prevention of Fertilization by Hyaluronidase Inhibitor.—Parkes shows that although it has become difficult to accept the idea that a bulk supply of hyaluronidase, coming from a mass of spermatozoa, is an essential prerequisite of fertilization, a possibility remains that the approach of a spermatozoon to the zona pellucida is assisted by its own individual supply of the enzyme, which may thus have some role in fertilization in some species. It was rational, therefore, to investigate the effect of decreasing the effective availability of the enzyme, by adding either hyaluronic acid complexes of hyaluronidase inhibitors to the semen before insemination. Apart from any question of application to contraception, the work on the effect of inhibitors is a means of investigating the role of hyaluronidase in fertilization, and perhaps that of other enzymes since the hyaluronidase inhibitors commonly used are far from specific. Parkes reports here the results of experiments on rabbits carried out with a new and powerful inhibitor Rehibin (tri-genticic acid, Compound 21P). Summarizing these experiments the author says that Rehibin, a highly active inhibitor of hyaluronidase, prevents fertilization when added at the rate of about 5 mg. per milliliter of semen in vitro to rabbit semen before insemination. Rehibin has no ordinary spermicidal action in the amounts used, and the effect on fertilization probably depends, at least in part, on its capacity to inhibit hyaluronidase. But this may not be the whole explanation. Attempts to inhibit fertilization by the administration of large amounts of Rehibin orally or by injection gave no reproducible positive results, but absorption of this large-molecule material may well have been negligible.

- Leprosy in Anglo-Egyptian Sudan East and Central Africa. R. G. Cochran.—p. 177.
 *The Leprotic Child in Africa. J. R. Innes.—p. 224.

The Child with Leprosy in Africa.—Innes carried out leprosy surveys in East Africa from 1946 to 1951. Most of the data obtained were reported previously. This paper is concerned with 1,492 cases of leprosy in children which were found in the natural or untreated state in a total of 7,072 cases of leprosy of all ages. The term child is used to include all persons of 14 years of age and under. The countries in which these 1,492 cases in children were found comprise Kenya, Tanganyika, Zanzibar and Pemba, Uganda, northern Rhodesia, and Nyasaland. Nearly every African tribe resident in these countries is represented in these children who were not in leprosariums but who came from the homes and villages and who at the time of discovery were living in the same conditions as their siblings who did not have leprosy. The fact that children accounted for 21% of all cases of leprosy indicates that leprosy is a living and continuing entity among these peoples. The sex ratio was 4:3, with males predominating. Analysis of the ages indicated a great increase between 5 and 14, which suggests that many must have sustained their infection at an early age. There were no indications that leprosy was acquired by one or a few momentary contacts, but rather by living in daily, and more especially nightly, contact with persons with leprosy in the family group. Leprosy in children and the young is mainly a problem of environment and living conditions. Protection of children from leprosy is an important key to the eradication of leprosy from a community. Leprosy in children

seems to begin either as a frank tuberculoid or lepromatous manifestation. Polyneuritic lesions, whether alone or complicating the main types, are considerably less frequent in these children. Although leprosy may be evanescent in childhood, the author believes that in a great proportion of the children leprosy would progress and cause infection of others. There is a lack of adequate accommodation in these countries for all existing cases of leprosy, but special attention to children is recommended as one of the most economic and fruitful forms of attack on the leprosy problem.

 Penicillin Sensitivity. P. W. Farmer.—p. 820.

Fertility and Sterility After Ectopic Pregnancy.—It is commonly believed that the occurrence of an ectopic gestation will in no way prejudice a woman's chances of producing a living child later on. In order to answer several questions on the relationship between ectopic pregnancy and sterility, Grant made studies on 259 women who had had ectopic pregnancy and who had been observed at two different departments of a Sydney women's hospital. The studies on these women and reports in the literature clearly show that the occurrence of an ectopic pregnancy is a major accident for the patient who wishes to produce a family, because, at the best estimate, only one-third of such patients will ever succeed in having a live baby, and in many groups the obstetric prognosis is much worse. Some investigators found that only one in every six of such women had a live baby during the rest of their life. Inquiry into the causes of this sterility reveals that it is located in the Fallopian tubes in 67% of the cases reviewed here and that most likely the tubal factor is involved in 81% of the cases. The incidence of ectopic gestation in patients attending a sterility clinic is seven times the usual incidence, and the frequency of ectopic gestation in patients treated for tubal blockage by high-pressure insufflation is 25 times that found among other pregnant women. The alternatives are to do nothing or to operate. However, tubal plastic operations are not yet very successful. The damage to the residual tube in most of the patients who have had an ectopic pregnancy appears to have been the result of salpingectomy in 50% of cases. The other 50% suffered bilateral tubal damage at the time of the original septic lesion in the pelvis, which preceded the occurrence of the ectopic gestation. No patient has been adequately treated for an ectopic pregnancy until her one residual tube has been proved patent by subsequent insufflation with carbon dioxide or by salpingography with the use of an aqueous and nonirritating medium.

 *Postoperative Disease and Corticoadrenal Function. G. Ferraris and G. Massone.—p. 579.

Corticoadrenal Function in Postoperative Disease.—To test the role of the adrenals in the causation of the so-called postoperative disease, the authors studied the circulating eosinophils, the urine content of uric acid and creatinine, and the urinary excretion

of the 17-ketosteroids in 17 women in whom interventions for gynecologic disorders had been performed at the Novara school of obstetrics. A marked eosinopenia, which was paralleled by an increased ratio between uric acid and creatinine, was found immediately after the operation in most of the patients; the changes in the 17-ketosteroids were not so marked and constant, but their excretion was slightly increased. These alterations are ascribed to an alarm phase of the general adaptation syndrome of Selye. The surgical trauma, which stimulates the adrenal cortex to a degree proportional to its length rather than its gravity, determines a greater peripheral need for corticoids, the blood level of which is, therefore, decreased; the hypophysis reacts by elaborating a greater amount of corticotropin; and this in turn stimulates the adrenal to a greater production of corticoids. When the stress ceases, the hyperactivity of the hypophyseal-adrenal system decreases and these blood and urine tests are again normal. In the authors' patients the eosinophils increased to above the preoperative values only by the eighth day, whereas the acid uric-creatinine ratio had already become normal by the 24th or 48th hour. Complications of the postoperative course delayed this return to normal. The authors conclude that the presence of a marked eosinopenia and an increased ratio between acid uric and creatinine within the first 24 postoperative hours suggest that the function of the patient's hypophyseal-adrenal system is good and the neuroendocrine defense reaction to the intervention will be efficient. An immediate postoperative marked eosinopenia is sufficient to eliminate the hypothesis of corticoadrenal deficiency in cases of shock. On the other hand, an increased number of eosinophils and irrelevant changes in the acid uric-creatinine ratio immediately after the intervention suggest adrenal insufficiency and possibly a bad prognosis. Of prognostic value is also a premature or a late return of these blood and urine alterations to the preoperative values. These blood and urine determinations have postoperatively the same prognostic value that Thorn's test with corticotropin has preoperatively.

- *Value of Comparative Study of Serial Electroencephalograms in Etiologic Diagnosis of Various Cerebral Afflictions. S. Thiry.—p. 1572.

Dosage of Isoniazid in Children.—The authors were impressed by the innocuousness of large doses of isoniazid in children. Eighty-four children hospitalized for tuberculosis (tuberculous meningitis or simple primary infection) were treated with large doses of isoniazid (40 times between 20 and 30 mg. per kilogram of body weight, and 11 times between 30 and 40 mg. per kilogram of body weight); this treatment lasted for from two to seven months. Clinical tolerance was remarkable, and biological examinations revealed almost no evidence of renal or hepatic involvement, with the exception of six cases of mild disturbance in galactose clearance. These strong doses enable high concentrations of isoniazid to be achieved in the blood. The blood concentration of isoniazid of 2 or 3 mcg. per cubic centimeter for the classic daily dose of 10 mg. per kilogram is raised to 6 to 10 mcg. per cubic centimeter for a daily dose of 20 to 30 mg. per kilogram and vacillates between 10 and 25 mcg. for a daily dose of 40 mg. per kilogram. These elevated doses, which are well tolerated by children, seem to be very useful in serious cases, since only the blood concentrations thus obtained are capable of acting on strains of bacilli that are most resistant.

Serial Electroencephalograms.—The author describes three cases in each of which a study of electroencephalograms taken at intervals of a few days during the course of illness was the decisive factor in establishing a diagnosis of cerebral tumor (in two cases) or of cerebrovascular accident (in one case). This method was previously used by him in the study of cerebral thrombophlebitis, the differential diagnosis of thrombophlebitis and cerebral abscess, and the progressive localization of a diffuent cerebral abscess. It is emphasized that this study of consecutive electroencephalograms must be analyzed

in the light of other clinical findings and information about the patient; on the other hand, electroencephalography is a simple and harmless procedure that has great value in early diagnosis. In these three cases, cerebral arteriography and ventriculography showed no abnormalities, but the diagnoses made on the basis of the electroencephalograms were confirmed at operation in the case of the two cerebral tumors and by response to treatment with vasodilators, anticoagulants, and short waves in the case of the vascular disturbance.

- *Prevention of Operative Shock by Methonium Compounds in Visceral Surgery: Based on 120 Cases. Du Callar.—p. 1595.

Methonium in Prevention of Operative Shock.—The author's technique is described for the use of controlled hypotension with one of the methonium derivatives in patients undergoing various surgical operations of the viscera. He used the substance pentamethonium bromide (C-5) in conjunction with other neuroplegics—Diparcol (10-[2-diethylaminoethyl]-phenothiazine), procaine, and Phenergan (10-[2-dimethylamino-1-propyl] phenothiazine)—in order to achieve a polyvalent neurovegetative stabilization through multifocal neurovegetative blocking that is effective both centrally and peripherally. This stability is necessary as a supplementary aid to the methonium in blocking the severe reflex to splanchnic irritation. The 120 patients on whom these observations are based had had hysterectomies, gastrectomies, abdominoperineal amputations of the rectum, endothoracic surgery of the lung, esophagus, and heart, and peripheral operations of the face, neck, breast, etc. Vasoplegia and hypotension were moderate when this method was used; the spare in blood loss was evaluated as two-thirds. No postoperative shock was observed in any case, and it is felt that this method of using methonium derivatives yields a significant antishock effect.

Digestive Disorders from Phenylbutazone.—The authors personally saw three patients in whom severe digestive reactions developed subsequent to the administration of phenylbutazone (Butazolidin) as an antirheumatic. In the first patient, there was reactivation of an old duodenal ulcer with hemorrhages; in the second, epigastric pain, severe alimentary vomiting, melena, and hematemesis; and in the third, transient edema of the lower extremities, severe epigastric pain, and probable reactivation of a duodenal ulcer. These cases are consistent with those reported in the literature, and review of them all establishes that phenylbutazone can cause simple reactivation of an ulcer, digestive hemorrhages, digestive perforations, bouts of ulcerous activity representing the evolution of multiple ulcers, and probably even new ulcers. In view of the remarkable similarity between digestive disorders caused by phenylbutazone and those caused by cortisone and corticotropin, the authors feel that the hypothetical mechanism of disturbances following hormone therapy should be kept in mind, namely hypersecretion of hydrochloric acid in the stomach due to adrenocortical stimulation. Of all the other disturbances that

can be caused by phenylbutazone (edema, cutaneous manifestations, blood disorders, etc.), none seems to be as important as the digestive ones. It is emphasized, however, that in spite of their practical and theoretical interest, the actual frequency of these disorders must not be overestimated.

Excision of the Temporal Cortex for Epilepsy.—Of 38 patients without cerebral tumor who were operated on for epilepsy, 25 had epileptic manifestations shown anatomically and physiologically to originate in the temporal cortex. Five patients in whom the operation was limited to simple exploration were excluded from this series. Clinical and electroencephalographic criteria of localization were used; they proved to be more useful than roentgenographic criteria. Abnormalities of the regions in question were noted macroscopically at operation in 5 patients; in 4 of these and in 11 of the 15 remaining ones, lesions were discovered microscopically. There were no operative deaths in the entire group of 38 patients. Only 16 of the 20 who had temporal cortical excision have been followed up long enough to be included in this report (more than six months). Of these, nine had excellent results, with no epileptic signs occurring after operation; two had partial results, major epileptic phenomena being replaced by minor ones; and five were not benefited, i. e., the same types of epileptic manifestations as had been noted in them before surgery were also seen after it, regardless of whether or not the frequency of the attacks had abated. Some of the authors' conclusions follow. 1. The age and sex of the patient, the length of duration of epilepsy before surgery, and the existence or nonexistence of a macroscopically or even histologically observable lesion have no influence on the postoperative results. 2. At present, one cannot count on good results in temporal cortical epilepsy in which the attacks begin with aphasia. In cases in which this disorder is a secondary manifestation, cortical excision rectifying the primary disorder should interrupt the orientation of the attack toward the language zone. 3. The uncus must be removed when the initial manifestations are of an olfactory nature; its removal is advised in cases in which visceral phenomena are a factor or in which there are olfactory secondary manifestations. 4. The postoperative course as judged by the first 15 days and the examinations done during this period are of no value in the eventual prognosis, and failures are often judged too soon. The authors have had patients with eventual remissions who had epileptic attacks in the first two months after operation. 5. Seizures may occur during the first six postoperative months in connection with pyrexias of diverse origins. They are without prognostic significance and probably represent vasomotor percussions on the cortical scar. 6. The authors are in disagreement with authors such as Obrador who consider the addition of generalized epileptic manifestations to purely temporal cortical ones a contraindication to temporal cortical excision. 7. Excisions limited to gyrectomy give poor results. The entire epileptic temporal cortex must be considered as a single functional tumor. This concept seems to explain the alternation of various types of temporal cortical manifestations seen in many patients with epilepsy of temporal cortical origin. 8. The delta seen on the posterior bank of the excision after lobectomy appears to be of little importance. It seems to be futile to attempt to make these anomalies disappear, unless they are accompanied by rapid potentials of high voltage. 9. Electric coagulation should not be used in performing the excision. The excision must be complete. The authors attempted to prevent adhesions of the cortex and dura mater by laying an amniotic membrane between the two. They attribute the absence in their patients of new forms of disorders that could be caused by cortical excision itself to these technical details.

Funnel Chest in School Children: Frequency and Roentgenologic Findings. J. T. Kristensen and H. Marqvard.—p. 1696.

Mesantoin in Treatment of Epilepsy.—Of Fuglsang-Frederiksen's 67 patients—42 with idiopathic epilepsy, 19 with symptomatic epilepsy, and 6 with doubtful epilepsy—treated with Mesantoin (3-methyl-5,5-phenylethyl hydantoin), 25 were previously untreated or insufficiently treated and 42 had received regular treatment. The average observation time was 15 months. Because of the danger of toxic side-effects treatment with Mesantoin was started with a dose of 5 to 10 cg. At suitable intervals, under constant control of the blood, the dose was increased by 10 cg. at a time. If the patient had been given other antiepileptic agents, the dose of the earlier agent was as a rule decreased simultaneously with the increase in the Mesantoin dosage. The maximum Mesantoin dosage was 90 cg.; the average dosage was 35 cg. Improvement occurred in 47 patients, of whom 11 were free from attacks, 22 considerably improved, and 14 moderately improved; 11 patients were unchanged, 3 were worse, and in 6 the result could not be evaluated. Twenty-nine of the 42 patients treated regularly before they were given Mesantoin and 18 of the 25 previously untreated were improved. Good results appeared oftener in symptomatic epilepsy than in idiopathic epilepsy; in doubtful epilepsy the results were poor. Improvement was independent of the duration of the disorder. There were toxic reactions in only one patient; in a patient treated with Mesantoin for three months, the leukocyte count steadily decreased to 1,880, without other abnormal blood changes, and on withdrawal of the Mesantoin, the leukocyte count gradually returned to normal. Focal seizures and petit mal and psychomotor attacks seemed to react more favorably to Mesantoin than grand mal seizures.

Hemodynamics of Left Auricle in Mitral Stenosis.—Roentgen kymographic analyses of the auricular movements and phonocardiographic records of the heart sounds were made in four patients with pure mitral stenosis. The records were made while the patient was standing or reclining (with head lower). The following observations were made. 1. A decided protodiastolic ventral movement of the contour of the left auricle in the retrocardiac space suggests a slight stenosis of the mitral ostium. 2. The severer the stenosis, the closer the kymographic record of the protodiastolic ventral movement (E-F) approaches the plateau form, and it actually assumes a plateau shape in extreme cases. 3. Movement of the auricular contour dorsally during the diastole suggests a simultaneous mitral insufficiency. 4. By lowering the head, these observations can be clarified by increasing the venous inflow. 5. Simultaneous recording of the cardiac sounds permits a comparative estimation of the extent of the protodiastolic and presystolic evacuation of the auricle in various postures. The combination of these two procedures signifies further progress in being able to estimate the conditions of inflow and outflow in the left auricle.

BOOK REVIEWS

Peripheral Nerve Injuries: Principles of Diagnosis. By Webb Haymaker, M.D., Chief, Neuropathology Section, Armed Forces Institute of Pathology, Washington, D. C., and Barnes Woodhall, M.D., Professor of Neurosurgery, Duke University School of Medicine, Durham, North Carolina. Second edition. Cloth, \$7. Pp. 333, with 272 illustrations. W. B. Saunders Company, 218 W. Washington Sq., Philadelphia 5; W. B. Saunders Company, Ltd., 7 Grape St., Shaftesbury Ave., London, W.C.2, 1953.

War, with its mutilating wounds, provides a much greater opportunity to study injuries to the peripheral nerves than does civil life. From such rich clinical experience the authors have written a monograph on the normal anatomy and the methods of recognizing dysfunction of the peripheral nerves. The first edition of this book, published during World War II, was a useful and popular guide for medical officers of the armed services. From further experiences in the treatment of military and civilian nerve wounds in the past decade, the authors have accumulated and incorporated new information in this second edition. Thus the subjects of pain, contractures, correlation of lesions with clinical evidences of nerve injury, and newer knowledge of the anatomical arrangement of the peripheral nerves are elaborated. An up-to-date list of references is appended.

The authors describe the motor, sensory, autonomic, and reflex changes resulting from injury of the roots, plexuses, and peripheral nerves in a concise manner. The anatomic aspects of the subject are clearly depicted by line drawings, and the clinical findings are shown by excellent photographs. If one were to criticize the monograph, perhaps the brevity with which certain subjects are discussed might be mentioned. Thus, the technical examination of injuries of peripheral nerves by electromyography, intraneural stimulation, and electrical examination—which some maintain were the most important developments in peripheral nerve injuries to come out of World War II—is covered in three pages of text. The conciseness may have led to some lack of clearness, for the correlation between pathological changes and the five clinical syndromes described as the result of nerve injury are not sufficiently documented to seem valid. Only rare errors of fact are noted; perhaps the most obvious is the statement that the sympathetic innervation of the upper extremity is derived from preganglionic fibers taking origin from the third to sixth thoracic nerves and perhaps from the second and seventh. There is good evidence that the first thoracic nerve and probably the eighth cervical also contribute to the sympathetic innervation of the arm. But these defects are minor and detract little from the general excellence of the monograph, which is well written, authoritative, and up-to-date. It should be a valuable reference book for all students, and a constant companion for physicians and surgeons who frequently treat traumatic cases.

Applied Anatomy and Kinesiology: The Mechanism of Muscular Movement. By Wilbur Pardon Bowen, M.S. Seventh edition revised by Henry A. Stone, M.S., Supervisor, Department of Physical Education, University of California, Berkeley. Cloth, \$5.50. Pp. 462, with 261 illustrations. Lea & Febiger, 600 S. Washington Sq., Philadelphia 6, 1953.

This attractively bound and profusely illustrated book gives a detailed account of muscular activity and the analysis of skills, especially in athletics. In addition to fundamental information on the theoretical mechanics, anatomy, physiology, and chemistry of muscular movement, the book suggests topics for reading and problems for experimental investigation that should be inspiring to students of the subject. Teachers who write textbooks sometimes comfort themselves with the belief that classes are critical and that nothing escapes the eye of students. Errors and obscurities found in a seventh edition unsettle this belief. An example is the exposition of Bernoulli's principle (page 368), which is obscure if not erroneous; others are the mutilation of references in foreign languages (page 151)

and minor errors like the phrase "this phenomena" (page 368). The comparison of "good" posture in a well-fed subject with that seen in an asthenic, poorly developed subject (page 327) will impress some as unfair and misleading, and the objection to "use of the arms when lowering oneself into a chair" (page 438) seems odd. The bibliographies at the end of each chapter appear not to include reference to the magnificent "Plastische Anatomie" of Mollier, which ought to be better known in this country, but they do include references to some dubious publications. These are minor flaws that can be corrected easily in future editions. The book as a whole can be recommended highly and will interest every medical reader.

Fundamentals and Applications of Clinical Oximetry. By Dr. W. G. Zijlstra. With foreword by Dr. R. Brinkman, Professor of Biochemistry, University of Groningen. Van Gorcum's medical library no. 117. Second edition. Cloth, 12.50 florins. Pp. 150, with 81 illustrations. Van Gorcum and Comp. N.V., Brink 10-12, Assen, Holland, 1953.

This book offers a wealth of information about instruments and methods used to determine the ratio of the amount of oxygen that the blood contains at any given time to the amount it can contain under certain standard conditions. The usefulness of the book to most physicians, even those active in clinical research, is limited by altogether needless obscurities. The misuse of abbreviations that characterizes so many recent books contributes to the difficulty here. For instance, the abbreviation "p. o. s." is not to be found in medical dictionaries, yet in this book it is used even in the table of contents. Since the book lacks an index, which might have been helpful, the reader's suspense is not relieved until page 11, on which he is told that the term means "percentage oxygen saturation." There is also no reason to use the abbreviation "E. E. G." if "electroencephalograph" is to be used only once in the whole book. In the same way, mathematics should be either clear and accurate or omitted entirely. When the author uses the words "function" and "integration," the conscientious student loses time deciding whether these words have their mathematical or their entirely unrelated physiological meanings. Primes (page 14) and periods (page 15) are sprinkled about in the formulas without evident reason, and the word "constant" (page 9) is used in a way that must be surprising to mathematicians. The neologism "isobestic," not to be found in recent textbooks and dictionaries, is defined on page 16. If the reader misses it or fails to retain it, more time is lost in locating it again and in wondering whether the word is restricted to the narrow sense assigned to it by the author or has a broader meaning. The text breaks off abruptly on page 139, and the reader is left to consider whether the few patients whose case histories are given were benefited by the elaborate machinery used to study the condition of their hemoglobin. The anti-scientific forces in modern society cannot be ignored, and not everyone is convinced of the value of research for the sake of research. A few pages of discussion and summary could be inspiring to younger scientists, would quicken the reader's appreciation of the vast amount of work represented in the tables and graphs, would justify it in the eyes of skeptics in other fields, and would certainly increase the value of the book to potential medical readers.

Insuring Special Class Risks: A Compend for the Life Insurance Agent. By Donald E. Yochem, B.S., M.Sc., M.D., Medical Director, Farm Bureau Life Insurance Company, Columbus, Ohio. Cloth, \$2.25. Pp. 77, with 2 illustrations. Insurance Research & Review Service, Inc., 123 W. North St., Indianapolis 9, 1953.

This book explains in nontechnical terms the reasons why some applicants for life insurance are required to pay premiums higher than those that are predicated on standard mortality tables. Many applicants for life insurance who were considered uninsurable several years ago are accepted today. This is one of the many benefits resulting from advances in medical science. Suggesting the term "special class risks" in

lieu of "substandard risks," the author outlines several of those physical impairments that necessitate special premium consideration. The five chapters cover the selection of risks, preliminary appraisals of doubtful risks, medical and non-medical applications, the viewpoints of clinical and life insurance medicine, and impairments and their effect on ratings and insurability. The purpose of special class ratings is to help applicants get needed insurance protection on the most favorable basis rather than to deny coverage. This problem is of interest to increasing numbers as evidenced by the estimate that over 12 billion dollars of extra-risk life insurance is now in force on more than 5 million policies. Although the author designates this book as a compend for the life insurance agent, the subject is of interest to field and home office insurance personnel (including medical examiners) as well as to those physicians who are interested in the subject of substandard life insurance risks.

Parsons' Diseases of the Eye. By Sir Stewart Duke-Elder, K.C.V.O., Ph.D., M.D., Surgeon-Oculist to Queen. Twelfth edition. Cloth. \$8. Pp. 606, with 487 illustrations. The Macmillan Company, 60 Fifth Ave., New York 11, 1954.

Long a standard textbook for undergraduate medical students and general practitioners in Great Britain, this treatise has never been widely distributed in the United States. In this new edition, revised and largely rewritten by Duke-Elder, the master's touch is evident in the clear, concise phraseology. Adequately illustrated with excellent drawings and photographs, some in color, the book may be studied and read with pleasure and profit not only by the medical student and general practitioner but by the neophyte in ophthalmology as well. Prepared apparently with a view of the American market, the book makes minimal mention of purely British pharmacological products. Fully up-to-date on modern therapy, it also includes discussions of some of the more recent advances in the physiology of the eye. For purely undergraduate teaching the section on surgery might have been further condensed or eliminated and some other portions of the book abbreviated, but it may be that these will stimulate the exceptional student or serve as a reference work for the practitioner who is not an ophthalmologist. There has been a recent increase in the number of textbooks on ophthalmology at this level. This new edition of a well-established book will prove a forceful competitor in the field.

Die Zuckerkrankheit: Leitfaden für Studierende und Ärzte. Von Prof. Dr. Ferdinand Bertram, Chefarzt der medizinischen Klinik des allgemeinen Krankenhauses Langenhorn, Hamburg. Fourth edition. Cloth. 19.80 marks. Pp. 175, with 25 illustrations. Georg Thieme Verlag, Diemershaldenstrasse 47, (14a) Stuttgart-O; American agent—Grune & Stratton, Inc., 381 Fourth Ave., New York 16, 1953.

In the six years since the last edition of this guidebook for students and practicing physicians, new ideas and new concepts have especially affected our attitude toward pathogenesis, treatment, and prognosis in diabetes. This provocative text attempts to relate these advances to present-day practice. The first half of the book is devoted to basic knowledge regarding metabolism and especially anabolic metabolism. A summary of the highly complicated chemistry of carbohydrate metabolism is well described, with special reference to the regulation of the blood sugar level. Experimental diabetes and the newer data obtained from the study of the anterior pituitary and adrenal secretions are well presented. Particular stress is placed on the studies of the alpha cells in the islands of Langerhans. Illustrations in the form of pathological sections or clinical features are notably few.

Diabetic retinitis and glomerulosclerosis are regarded as unrelated to the severity of diabetes or its treatment but dependent only on its duration. This point of view gives little weight to the increasing evidence that these lesions, as well as the premature capillary and arteriolar manifestations of diabetes, are much more frequent in the severe diabetes of young patients than in the mild diabetes of middle-aged patients. The importance of control of diabetes is not adequately presented. Among the complications presented are pregnancy,

gangrene, infection, and coma. A special classification is given to cardiovascular coma and renal coma. It is refreshing to note the author's emphasis on the diet as the fundamental cornerstone of all diabetic treatment. He emphasizes that the diet should be relatively high in carbohydrate and limited in fat at all ages. In adults the average carbohydrate in the daily diet is 250 gm., and in children 250 to 350 gm. of carbohydrate are prescribed with fat in amounts varying from 60 to 80 gm. The provision of a diet rich in vitamins and in basic minerals is important. Insulin is to be prescribed for all children. Some authors speak of 50 to 60% of diabetic patients receiving insulin. Bertram notes that 85% of the patients treated in the Joslin Clinic receive insulin and that in his own practice 80% of his patients are treated with insulin. Absolute indications include coma and precoma, emergencies such as acute infections and operations, and patients in whom, with dietary treatment alone, satisfactory adjustment does not occur. He notes differences in the treatment of coma in different clinics and prefers the early use of glucose. In this respect, he has omitted reference to some of the recent reports (notably the New Haven studies) indicating certain dangers from disturbance in osmotic equilibrium produced by this treatment. This volume may be read with profit by any physician interested in present-day treatment of diabetes.

Modern Trends in Diagnostic Radiology (Second Series). Edited by J. W. McLaren, M.A., M.R.C.P., F.F.R., Radiologist, X-Ray Department, St. Thomas's Hospital, London. Cloth. \$18. Pp. 413, with 359 illustrations. Paul B. Hoeber, Inc. (medical book department of Harper & Brothers), 49 E. 33rd St., New York 16, 1953.

An interesting series of articles on new or revised methods of roentgenologic diagnosis is presented in this book by some of the world's leading radiologists. There are chapters on recent designs in radiological apparatus, protection in diagnostic radiology, volume doses sustained by the patient in diagnosis, and the place of radiology in research. There are several articles on contrast angiography and arthrography, bringing many of the new developments in these fields up to date. Certain aspects of lesions of the small and large intestine, of the urinary tract, and of the pancreas are reviewed. There are some excellent chapters on cerebral angiography, pneumoencephalography, and myelography. After a chapter on hysterothyrography in cancer of the uterus, the volume terminates with a section on the law relating to the practice of radiology. The first volume of this series appeared five years ago, and this (the second) maintains the high standards then set. It should be enjoyed by clinical radiologists.

Clinical Management of Behavior Disorders in Children. By Harry Bakwin, M.D., Professor of Clinical Pediatrics, New York University, and Ruth Morris Bakwin, M.D., Associate Professor, Clinical Pediatrics, New York University, New York. Cloth. \$10. Pp. 495, with 14 illustrations. W. B. Saunders Company, 218 W. Washington Sq., Philadelphia 5; W. B. Saunders Company, Ltd., 7 Grape St., Shaftesbury Ave., London, W.C.2, 1953.

This volume is designed as a practical textbook and guide not only for the physician but also for professional workers in the field of child psychology. The authors have kept in touch with all new work in the field and treat the material in a competent manner. The language is simple and direct. The first chapters are devoted to a description of normal growth and development. The behavior disorders discussed are those due to all causes—whether chronic disease, physical disability, deviation from the average mentality, developmental aberration, emotional distress, or other factors. Common problems, such as eating habits, enuresis, thumb-sucking, and difficulties of adolescence, are included, as well as many disturbances less often encountered. The diagnostic section contains detailed material on history-taking, interviewing, examination, drawing tests, and projective techniques. The authors follow a common sense approach with the inclusion of a minimum of theoretical material. The arrangement of material makes it easy to locate topics, and the index is adequate. There is an excellent bibliography at the end of each section. The volume is most attractive and readable. There is a minimum of typographical errors. This book can be recommended.

Hypertensive Diseases: Causes and Control. By Henry A. Schroeder, M.D., F.A.C.P., Associate Professor of Medicine and Director, Hypertension Division, Department of Internal Medicine, Washington University School of Medicine, St. Louis. With contributions from Gregory S. Gressel, M.D., Dean F. Davies, Ph.D., M.D., H. Mitchell Perry, Jr., M.D., and Donald F. Gibbs, M.B.Ch.B., M.R.C.P. Cloth. \$10. Pp. 610, with 167 illustrations. Lea & Febiger, 600 S. Washington Sq., Philadelphia 6, 1953.

This impressive volume is written in a clear and forceful style, and the material is well arranged. The book aims to be a comprehensive survey of the mechanism and management of hypertension to guide the practitioner's thought and action. Unfortunately for this purpose the survey, while extensive, is at times too selective. It centers unduly around the author's views and experiences with no proportionate regard or evaluation of the views of others. The author's reason for doing this is that he aims deliberately to be provocative. This is of no concern, however, from the practitioner's point of view, since the practitioner will often be at a loss to know what is instructive and what he should be provoked about. Possibly some format like an Eugene O'Neill play in which conscious utterances and unconscious deliberations are clearly delimited might be helpful. The book lacks balance and loses the value that a more objective statement might have had. This does not detract from its stimulation to the specialist.

For example, few would agree that sulfhydryl-containing substances are specifically antipressor or that the mystery of biogenesis of renal hypertension lies in the nature of the action of 1-hydrazinophthalazine. The term hyphex for combined treatment with hydrazinophthalazine and hexamethonium is ingenious and convenient but has a strong proprietary air that puts it in questionable taste. The claim that this treatment is the "first effective and specific method" for the treatment of hypertension is not generally admitted. To the reader willing and able to select and balance the points of view that are presented, the book will represent a useful clarification of some aspects of the field, but most readers will find themselves even more at a loss than before.

Physiological Acoustics. By Ernest Glen Wever and Merle Lawrence. Cloth. \$10. Pp. 454, with 148 illustrations. Princeton University Press, Princeton, New Jersey; Oxford University Press, Amen House, Warwick Sq., London, E.C.4, 1954.

This book, written by two distinguished leaders of research on hearing, concerns itself with the ear as an acoustic instrument. The first three chapters consider the anatomy of the ear, the physical nature of sound, and the methods that have been employed for the study of auditory processes, thus bringing into focus the problem of the basic function of the middle ear mechanism. Special attention is given to a formulation of the principles governing the operation of the middle ear as a mechanical transformer, to the problem of how energy in the form of aerial waves is effectively used by the ear, and to the question of distortion in the ear. Two chapters are devoted to derangements of the conductive mechanism and the forms of deafness that result, special attention being paid to otosclerosis. Discussion of various topics is presented systematically, and existing facts and more credible opinions reviewed critically. Many results represent investigations carried out by the authors over a period of years. Some of the recent experiments, designed to answer questions arising during the writing of the book, are reported for the first time. This book should appeal greatly to all serious students of the ear.

Health Services for the Child. By Edward R. Schlesinger, M.D., M.P.H., Associate Director of Medical Services, New York State Department of Health, Albany. Foreword by Herman E. Hilleboe, M.D. McGraw-Hill Series in Health Science, Amos Christie, M.D., consulting editor. Cloth. \$7.50. Pp. 403, with 12 illustrations. McGraw-Hill Book Company, Inc., 330 W. 42nd St., New York 36; 95 Farringdon St., London, E.C.4, 1953.

The author indicates that the mental, physical, emotional, and spiritual needs of the child must be met if we are to furnish satisfactory health services for the child. He describes the general problems to be met, as well as special ones such as mental retardation and cerebral palsy, and describes how best to meet these problems. The field of maternal and child health, the factual description of the development of various services, and the way in which the resources of the home, medical and nursing skills, school contributions, special training, and public

health support can be made available are well described. An adequate bibliography is included. The subject matter is presented in a clear and easily readable manner. The book is highly recommended to all workers in any part of the field of child health care. Voluntary help and facilities of governmental agencies at all levels from local to national are clearly described. Ex-President Hoover's "Children's Charter" is quoted in its entirety, and the author accurately reports that this conference "in 1930 represents the high water mark of White House conferences."

Pediatric Gynecology with Sections on Urology and Proctology. By Goodrich C. Schauffler, M.D., Assistant Clinical Professor of Obstetrics and Gynecology, University of Oregon Medical School, Portland. Third edition. Cloth. \$7.50. Pp. 318, with 76 illustrations. Year Book Publishers, Inc., 200 E. Illinois St., Chicago 11, 1953.

This new edition of a useful text in this special field is timely and brings up-to-date information. The problems peculiar to the female child during growth, puberty, and adolescence have received more careful consideration in this edition. The various chapters consider the anomalies, diseases, and physiological alterations of the external and internal genital organs. A chapter on embryology by Dr. G. Gordon Roberts has been added, pediatric urology is discussed by Dr. Clarence B. Hodges, and the considerations for surgery of children are discussed by Dr. C. W. Brunkow. There are chapters devoted to the social service and medicolegal aspects of this special phase of gynecology. Those who have read the second edition of this book will welcome the new one.

Infrared Absorption Spectra of Steroids: An Atlas. By Konrad Dobriner, E. R. Katzenellenbogen and R. Norman Jones. Preface by C. P. Rhoads. Cloth. \$11.50. Pp. xlv, with 308 charts. Interscience Publishers, Inc., 250 Fifth Ave., New York 1; 2a Southampton Row, London, W.C.1, 1953.

This atlas contains not only the infrared absorption spectra of the steroid hormones and their derivatives and metabolites but also a number of representative curves of bile acid esters, cardiac aglycones and steroid alcohols, alkaloids, and sapogenins. Most of the 308 spectral curves collected here are not available in the published literature but were determined specifically for inclusion in this volume so that investigators in this field could use them for identification purposes. A short introductory chapter on experimental technique and on the use of the curves for identification purposes is also included. The volume contains an adequate index.

Trattamento del malato chirurgico: Fisiopatologia e clinica dell'operato. Dal Prof. Luigi Imperati, direttore incaricato dell'Istituto di patologia chirurgica dell'Università di Sassari. Prefazione del Prof. Luigi Torraca, direttore della Clinica chirurgica dell'Università di Napoli. Cloth. 7000 lire. Pp. 684, with 116 illustrations. Casa editrice V. Idelson di E. Gnocchi & F., Via E. de Marinis 19, Naples, 612, 1953.

After the introduction to this new and interesting book, in which the author speaks of different phases of the evolution of surgical therapy, he expresses the opinion that surgical intervention is not only a problem of operative technique but also of physiopathology and medical therapy. He gives a clear and complete analysis of what the modern surgeon should know about the postoperative patient. He discusses the patient's physical, humoral, hemodynamic, and metabolic conditions, particularly the changes before and after surgery, and the operative risk and its causes.

Believing with Osler that the surgeon should be a well-informed physician, he comments on medical therapeutic aids, sedatives, stimulants, hemostatics, anticoagulants, chemotherapy and antibiotics, infusion and transfusion therapy, and physiotherapy. In the second part of the book, he treats extensively anesthesia and its many problems, particularly shock, for which he uses a formula involving "the circulatory quotient." This formula indicates the peripheral circulatory condition of the surgical patient before operation. Regarding organic and functional cardiac, renal, metabolic, endocrinic, and dyscrasic diseases, he discusses the operative risk and the prognosis. Post-operative complications and the surgery of the different organs are described. There is a chapter by Professor Guidetti on surgery of the central nervous system. This volume is recommended to all surgeons who read Italian.

QUERIES AND MINOR NOTES

CRACKING JOINTS

TO THE EDITOR:—For years I have been searching for information on the biomechanics and the clinical and pathological implications of the phenomenon of sound produced by the "cracking" of a knuckle or when the arms are over-extended. What is the explanation for the temporary feeling of relief in the joints? What is happening during the interval when the feeling of relief is waning and during which one cannot get the joint to "crack"? Why does the joint "crack" more frequently in cold and wet weather? I have seen patients who, by positioning limbs and trunk in different poses and then contracting muscles, "crack" almost every joint in the body.

M.D., New York.

This inquiry was referred to two consultants, whose respective replies follow.—ED.

ANSWER.—Several theories have been advanced as to the mechanism of joint "cracking," but apparently none has been substantiated by experimental observation. These include the slipping of a tendon or ligament over a bony prominence when the joint is moved or stretched, the pulling apart of opposing joint surfaces, and the forcible sliding of a tendon in or out of its sheath. The temporary feeling of relief may be due to relaxation of muscular tension, with the subject unable to produce the "cracking" during the period of relaxation. It is also possible that the tendon, if involved, becomes edematous from the "cracking" and thus relaxed. With the loss of edema, a state of tension may resume that again permits the "cracking" process. If cold or wet weather contributes to muscular tension, then "cracking" would be facilitated. It seems unlikely that the sound is produced by actual breaking of fibrous tissue.

ANSWER.—The phenomenon of "cracking" joints is probably not perfectly understood but several facts are known about it. Most joints that "crack" are not the site of any serious pathological process. Rather, there is some slight aberration in the contour of the joint, such as a roughening or irregularity, over which some structure of the joint passes; after that structure has passed the irregular spot it is restored to normal position, with the accompanying audible or palpable "cracking." Why joints "crack" more in cold weather or wet weather than at other times is not known, and it may not be a fact that they always do this. In cases in which relief is obtained from stretching, probably some mild capsular contracture tends to make the joint slightly uncomfortable and the discomfort is relieved by stretching the capsule. Of course, in severely deranged joints there is often a good deal of audible and palpable crepitus. This obviously is attributable to the irregularities of the joint, and relief is not obtained by movement of the joint. Rather, the opposite is often true.

DIAGNOSIS OF DRUG ADDICTION

TO THE EDITOR:—Are there any simple pathognomonic physical findings by which the family physician's suspicion of narcotic addiction may be supported? Tell-tale needle scars are seldom seen now except in the chronic habitué.

M.D., California.

ANSWER.—There are no pathognomonic physical findings by which the diagnosis of addiction to narcotic drugs of the morphine type can be made as long as the addict is taking the drugs. Such findings as needle marks (especially if fresh), miosis, somnolence, and behavior change, while suggestive, are not diagnostic. Tests for the presence of narcotics in urine

are very helpful but are very difficult, dragged out, and also not usually available to the average physician. The diagnosis may be made in one of two ways. The patient can be isolated in a drug-free environment and observed for the appearance of signs of abstinence. These should be evident and unmistakable within 24 hours, unless the patient has succeeded in smuggling narcotics into the isolated environment. The procedure requires familiarity with signs of abstinence. These have been described by Vogel, Isbell, and Chapman (*J. A. M. A.* 138:1019-1026 [Dec. 4] 1948). Diagnosis may also be made by precipitating abstinence with a small dose of N-allylnormorphine (Nalorphine). The method of using this drug has been described by Isbell (*Merck Report* 62:23-26 [April] 1953).

CONVULSIVE THERAPY

TO THE EDITOR:—I have made observations on the electroshock treatment of 24 emotionally disturbed patients in three midwest hospitals. I observed 48 hour results following 187 electroshock treatments. The condition of 81% became worse, of 10% improved, and of 11% unchanged. Some investigators have proved that petechial hemorrhages and small focal necroses may result. Some British investigators have observed similar brain lesions. Please express an opinion.

M.D., Indiana.

ANSWER.—Evaluation of the convulsive treatment should not be based on observations 48 hours after the treatment. The reason for this is, as Meduna reported 19 years ago, that 24 hours after the convulsive treatment the patient's level of consciousness approaches qualitatively that of a postconvulsive confusion; 48 hours after the treatment the patient's conscious state of mind is a blend of the original psychotic state and of residuals of an epileptic confusion. Changes, if any, should be evaluated only on the third day after the convulsive treatment. Changes cannot be appraised as beneficial following a single convulsive treatment. Sometimes 4 or 5 or even 15 or 20 treatments are necessary to produce beneficial changes in the patient's pathological state.

Convulsive therapy was introduced as a treatment for schizophrenia, but the spectacular results in affective disorders overshadowed its effectiveness in schizophrenia. The emotional disorder very rarely, and only in cases selected with extreme caution, is an indication for convulsive treatment. The main indications for convulsive treatments are (1) manic depressive disease (80 to 100% remissions in the depressive phase and 70 to 90% remissions in the manic phase) and (2) the involutional psychoses such as involutional melancholia, depressions in old age, and involutional psychosis of the paranoid type (86% remissions in involutional melancholia and 43% in the paranoid group). In schizophrenia of less than six months' duration, 68% recover, and in schizophrenia of six months' to two years' duration 41% recover after the proper administration of convulsive therapy.

The complications and dangers of the treatment are well known to the psychiatrist. Cerletti and de Bini in Italy, studying dogs receiving electric therapy comparable to that given to human beings, found no destructive alterations of cells, no hemorrhages, and no necroses. In this country Barrera, Lewis, Pacella, and Kalinowsky reached the same conclusion on investigating brains of monkeys treated with electric shock. Ebaugh has described a patient in whom death occurred during the first convulsion. The changes he found were reversible and could not have interfered with brain function.

Convulsive treatment is an extremely useful tool in the hands of the psychiatrist. Its proper indications and contraindications can be looked up in any textbook dealing with the subject. Proper basic information can be obtained from "Shock Treatments, Psychosurgery, and Other Somatic Treatments in Psychiatry" by Kalinowsky and Hoch (ed. 2, New York, Grune & Stratton, Inc., 1952).

SYPHILIS

TO THE EDITOR:—A diagnosis of syphilis was made on the basis of a 4+ Wassermann test about four years ago. While the patient's history is confusing, it is possible that an insignificant lesion on the penis 15 years ago could have been the atrium of infection. Following this, however, there were several negative Wassermann tests and one moderately positive one. The treatment has been a combination of long courses of both the arsenic and bismuth preparations followed by six courses of from 10 to 15 million units of penicillin intramuscularly until the blood serum Wassermann reaction was normal. One spinal fluid test during the height of the positive blood Wassermann reaction was absolutely negative. No other spinal punctures have been made since. One year following the negative Wassermann reaction another blood serum test showed a 4+ Wassermann reaction. There are no other findings. Hence my questions: 1. What is the prognosis if treatment with penicillin is continued? 2. At what intervals should injections of 10 to 15 million units of penicillin be given? 3. Do you suggest combining this with any other remedy? 4. Have any of the newer antibiotics proved definitely spirocheticidal?

M.D., Arizona.

ANSWER.—The data furnished in this query are incomplete, as the only evidence that the patient has syphilis is the positive serologic test for syphilis. As this has varied from negative to positive, it may be that the test is biologically false positive. Therefore, it would be well to have a *Treponema pallidum* immobilization test done to establish the fact that the patient does have syphilis.

In regard to the four questions: If the patient does have syphilis, if the spinal fluid is negative, if he has no evidence of cardiovascular syphilis, and the impression is that he has had the disease for 15 years, the prognosis is good, whether or not he has any treatment. In other words, the continued administration of penicillin at the rate of 10 million units in a 12 day period is not of value in patients with latent syphilis in reversing the serologic tests to negative and therefore there is no justification for its further use. It has likewise been shown that penicillin need not be given in combination with any other remedy, as it is effective alone in early, visceral, and neural syphilis. However, it does not help the reversal of Wassermann-fast serologic tests to negative and accordingly should not be given in repeated courses. The other antibiotics, such as chlortetracycline (Aureomycin) and oxytetracycline (Terramycin), have been proved to have value in the treatment of syphilis but are not indicated in this patient because of the fact that the treatment has been more than adequate to date.

CARDIAC ARREST

TO THE EDITOR:—1. With reference to anoxia as a factor in cardiac arrest, is there a critical point in oxygen saturation or deficiency in the circulation that predisposes to or would precipitate cardiac arrest? 2. With reference to anemia as a factor, is there some point or percentage of gram level in hemoglobin that one can accept as an indication for preoperative transfusion of whole blood prophylactically in major surgery when no more than ordinary blood loss is anticipated? 3. Does the giving of curare predispose to cardiorespiratory failure?

Santo S. Torcivia, M.D., Milwaukee.

ANSWER.—1. Anoxia is perhaps the commonest factor in producing cardiac arrest. The critical level scarcely exists as such, but anoxia added to other possible factors can bring about cardiac arrest. 2. The answer to this question is much the same as in 1. The hemoglobin content should be kept as close to normal as possible. Anemia plus anesthetic agents can precipitate cardiac arrest when either group of factors alone would not produce arrest. 3. I use the Rand-Wolfe respirator for all operations on the heart. My opinion is that curare does not predispose to cardiorespiratory failure. I think the surgeon is the responsible person for the operation and all other services connected with it. The patient selects the surgeon and places responsibility in him. He does not select the anesthetist, and he expects the surgeon to provide proper anesthesia.

EXTRACTION OF TEETH IN HEMOPHILIACS

TO THE EDITOR:—A 35-year-old hemophiliac has a septic mouth and his 15 remaining teeth should be removed. The last attempt at extraction resulted in hemorrhage that required transfusions of 7,000 cc. of blood. There is a dispute among the hematologist, the exodontist, and the man's dentist regarding whether to remove one tooth at a time or to remove all at once. What is the best method of handling this case?

M.D., Pennsylvania.

This inquiry was referred to two consultants, whose respective replies follow.—Ed.

ANSWER.—The method of choice for the extraction of teeth in hemophiliacs is exfoliation by means of thin rubber elastics as described recently by Massler and Aguirre (Massler, M., and Aguirre, B.: Exfoliation of Teeth by Means of Elastic Bands, *J. Dent. Child.* 19(2):56-59 [Jan.] 1952) rather than by extraction. There is an advantage in the extraction of all the teeth at one time, since the number of hemorrhagic episodes is thus reduced. The patient should be carefully prepared by (1) loosening of teeth with rubber ligatures to reduce operative trauma; (2) transfusion to reduce bleeding time to less than 15 minutes; and (3) hospitalization prior to extraction.

ANSWER.—Extractions should not be limited to one tooth at a time, especially in a case in which removal of 15 teeth is indicated. The necessity for control of hemorrhage on 15 different occasions would be most impractical and an unnecessary hardship to the patient from the standpoint of both time and cost; it is very doubtful, also, that it would reduce the risk. Generally speaking, it is advisable to extract the teeth situated in continuous series. The reason for this is that the region that presents most difficulty in local control of hemorrhage is invariably adjacent to the tooth that remains. Insofar as local control of hemorrhage is concerned, it may be advisable in many instances to confine extraction to one jaw only. This would require not more than two sittings.

KELOIDS FOLLOWING OPERATIVE SCARS

TO THE EDITOR:—In a previous issue THE JOURNAL mentioned the use of hyaluronidase for treatment of keloids following operative scars. A therapy with this preparation by Cornbleet was mentioned. What is the specific technique used?

Leon Badler, M.D., Bronx, N. Y.

ANSWER.—Cornbleet's method is as follows: A solution of 150 units of hyaluronidase in 1 cc. of saline solution or larger quantities in the same proportion is used. The entire keloid is distended by injection of the solution at intervals over the entire surface. Tuberculin or lock-type syringes should be used to overcome early resistance of older keloids. The injections should be repeated once or twice a week. Early keloids are ready for surgery after two to four weeks, but older ones need as much as three months' preparation. Hyaluronidase treatment is resumed when the skin edges heal together, while the usual routine radiation is administered simultaneously. With early keloids no surgery is necessary, and radiation therapy with x-rays or radium may be begun after a week or two of preliminary hyaluronidase treatment. Enzyme injections should precede each individual radiation exposure. The normal skin should be irradiated for a distance of 1 in. (2.5 cm.) beyond the border of the keloid.

ANTIBIOTICS AND RABIES

TO THE EDITOR:—Do the antibiotics suppress Negri bodies, so that on postmortem examination of the brain of a rabid animal these bodies may be absent or immature?

Bernard Greenberg, M.D., Brooklyn.

This inquiry was referred to two consultants, whose respective replies follow.—Ed.

ANSWER.—To the present time, no known antibiotics suppress Negri bodies under usual conditions (Fagan, R.: *Proc. Soc. Exper. Biol. & Med.* 81:213-214, 1952). Other studies, however, indicate that Negri bodies may be suppressed by the early administration of known high-titered rabies antiserum or rabies vaccine, both in cases of experimental fixed virus infection and in street virus infection.

ANSWER.—So far as can be determined, there is no evidence that any of the presently available antibiotic agents exert any virostatic or viricidal action against the agent of rabies. For this reason, one would not expect the administration of an antibiotic to affect the formation of Negri bodies in the animal infected with the rabies virus; there should, therefore, be no difference in the Negri bodies in the brain of animals that have not been treated and those that have received any of the presently available antibiotic agents.

PAIN IN HEMIPLEGIC AREA

TO THE EDITOR:—In the reply to the question concerning pain in a hemiplegic area in *Queries and Minor Notes*, Dec. 12, 1953, it occurred to me that describing "almost continuous pain in the entire hemiplegic area" to spasticity is quite unusual. In addition, the further statement that this might be due to "vascular or visceral pain following the path of blood vessels" seems meaningless. In view of the fact that the entire hemiplegic area is involved, it would seem most likely that this patient presents an example of the "thalamic syndrome." As such, anterolateral cordotomy would certainly not be effective. In addition, the statement is further made "Since the pain is of visceral type, it should respond to procaine intravenously." I am at a loss to understand why such a differential point should be made, as the inference is that visceral pain and procaine relief are somehow related. If the patient mentioned has a thalamic disturbance, I fear that any therapy will prove difficult. The last point that interested me is the inference that the hemiplegic patient is more sensitive to opiates in terms of blood pressure response, because of a sensitivity at the peripheral receptors, the blood vessels.

John B. Pfeiffer, Jr., M.D.
Duke University School of Medicine
Durham, N. C.

The above letter was sent to the consultant who answered the original query and to an additional consultant whose comments follow.—ED.

TO THE EDITOR:—The following paragraphs clarify my previous remarks. The commentator must have reference to "central pain" rather than thalamic syndrome. Bonica writing on "central pain" classifies both the thalamic syndrome and pain owing to lesions of the spinal cord as "central pain." If the pain originates at the site of the severed spinothalamic tract fibers, then "central pain" is the proper term. Bonica has a section on central pain with lesions of the spinal cord that should be consulted.

C fibers that carry slow or burning pain presumably follow the pathways of blood vessels and frequently enter the spinal cord at levels well above the usual somatic dermatome. As an example, toenail bed pain, which is predominantly "C fiber pain," requires block of T_{11} and T_{12} dorsal roots for relief. The use of the term visceral was not intended in the sense of afferent fibers from viscera, but rather small diameter fibers that follow the pathways of blood vessels. If these fibers contribute to the pain of this hemiplegic patient, then procaine intravenously may give some relief and should be tried; it may be more effective than opiates without the addiction liability of the latter.

Patients receiving any of the potent analgesics intravenously show a rapid dilation of the conjunctival blood vessels and a tendency toward postural hypotension. This same phenomenon occurs after subcutaneous injection, but at a slower rate. I believe this is a persistent histamine-like effect, but others ascribe it to an acetylcholine-like effect. The concomitant cutaneous itching would favor the persistent histamine theory, which might also explain the increase in intestinal segmental movement and tone that occurs. The hypotension is sufficiently prominent in human trials so that normal subjects at bed rest almost never have nausea and vomiting while ambulatory subjects have postural hypotension and frequently have emesis.

TO THE EDITOR:—There are not enough details for one to attempt a complete resolution on the differences of opinion expressed by the person who answered the question and

the one who wrote in about it. I am dubious about the designation that the pain should be ascribed to thalamic sources. In the so-called thalamic syndrome, sensory loss, ataxia, and pain are usually seen together. The hyperpathia is never continuous, and it is generally evoked by a peripheral stimulus. Furthermore, many of the cerebrovascular lesions involve the thalamic region, but few present the picture given above. Finally, such patients are never seen in hospitals that utilize the services of physical therapists. There is much to indicate that the so-called pain is more "misery" or anxiety than real. Sensory pathways being as ill-defined as they are, it is rare that denervation is complete in all spheres, and protopathic sensations can and do reach the cerebrum from the joints of hemiplegics. This is often less than that which accompanies any disability which has immobilized a joint. Early and frequent movement of such joints will eliminate the complaint of pain. Late in the course of such cases it is essential that full ranges of motion be attained, but there will not be the assurance that all complaints will be abolished. I have personally relieved such pains by cordotomy in carefully selected patients, and I know of others who have had the same experience, especially when the complaints were confined to a single extremity. In a patient who is hopelessly involved in the emotional equivalents of severe disability, nothing short of frontal lobe procedures can be expected to be of help. It would be my guess that the patient in question has primarily an emotional problem and that the first approaches should be those of rehabilitation, with surgical considerations being reserved for the future. It is certainly possible to help this patient considerably.

The second part of the discussion centered around the inference that the pain was of a vascular nature. I believe that the primary difference is one of terminology. The "visceral" pain of Davis and Pollock is probably much the same as the "sympathetic" pain of many others. I thought that it was common knowledge that meperidine caused drastic drops in blood pressure, especially in hypertensive patients. I certainly see it often, in hemiplegia from causes other than cerebrovascular accidents as well. That there are vascular differences on the hemiplegic side is a well-documented fact (hemiedema, "trophic" changes, etc.). Whether these are equivalent to the demonstrations of White in regard to sympathetically denervated vessels would depend greatly upon the exact nature of the lesion in the brain. Those who have stimulated the various areas of the brain to induce sympathetic changes are aware of the intensity of the responses that are possible, especially from areas 13 and 14 on the orbital surfaces of the frontal lobes. There may be a "release" mechanism involved in given patients, just as Walker describes the protopathia of thalamic lesions. It would be of great help in attempting to resolve the differences to have a trial injection into the involved carotid artery of several cubic centimeters of procaine, but it would not give an answer to the academic points. Occasionally, procaine blockage of the cervical sympathetic nerves helps one reach some conclusions in regard to the nature of the symptoms. It would be my guess that the patient has a huge clot that is resolving slowly and that angiographic survey of the cerebral circulation would be a necessary prelude to much discussion. On a purely empiric basis, I would return to the original implication that the patient was allowed to become too incapacitated by his disease and has become a problem of salvage.

REMOVAL OF PERMANGANATE STAINS

TO THE EDITOR:—In reference to *Queries and Minor Notes*, on this subject in *THE JOURNAL*, Sept. 19, 1953, page 258, and Oct. 31, 1953, page 894, the use of sodium bisulfite appears to be inexpensive, safe, and very effective. It can be applied in powder form like any kitchen cleanser. When employed on the hands, it is recommended that it be removed by a weak acid such as vinegar.

PAUL EHRLICH: HIS CONTRIBUTIONS TO MEDICINE

A TRIBUTE AT THE CENTENNIAL OF HIS BIRTHDAY

Hans C. S. Aron, M.D., Chicago

Most great men in medicine are remembered because their names are connected with one fundamental discovery, with the description of one or several diseases, with important symptoms or signs, or with technical or operative procedures. Paul Ehrlich's contributions to medicine are so numerous that it is not possible to link his name with one particular achievement. In hematology, in immunology, and in chemotherapy (a means of treatment which he originated), Ehrlich established many basic facts, developed a number of fundamental methods, and coined a multitude of terms that have become the common property of the medical profession. They are used so frequently that the name of Paul Ehrlich now is seldom quoted in this connection. At the centennial of the birthday of this genius and pioneer, it appears to be appropriate to recollect those of his accomplishments that have withstood the test of time to the present day.

Paul Ehrlich was born March 14, 1854, in Strehlen, a small town in Silesia, Germany. A brilliant scholar at the gymnasium and an exceptional student in medicine, he had already started laboratory work of his own before graduation. At the age of 23, Ehrlich published his first scientific paper; he described a new type of cell that he had found, which he called *Mastzellen* or mast cells, a term used to this day. The discovery of the mast cells was the first practical result of Ehrlich's attempts to utilize the aniline dyes, recently created by the chemical industry, for staining purposes in histological studies. While he was a resident in internal medicine at the University Hospital in Berlin, called the Charité, he developed the basic methods used in modern hematology.

He devised the technique of preparing a thin layer of blood and applying the most suitable dyes to this smear when dry. All available dyes of various chemical character and many different mixtures of them were tested. For the first time Ehrlich studied the granulations in the protoplasm of the white blood cells. He found and characterized the eosinophils, the basophils, and the neutrophils (later called the polymorphonuclear white blood cells). He described, furthermore, the myelocytes, the large mononuclear leukocytes, and the transitional leuko-

cytes. He showed how to distinguish three types of red blood cells—the normoblasts, the megaloblasts, and the microblasts or poikiloblasts. With his command of Greek and Latin, Ehrlich easily found a characteristic name for each type of blood cell that he discovered. Most of these terms were universally accepted and are used unchanged to the present day. In 1887, Ehrlich showed how it was possible from a drop of blood to recognize lymphatic leukemia and to distinguish it from the bone marrow cell leukemia, later called myeloid leukemia. In the following year, Ehrlich described a new type of anemia, which he called aplastic anemia, and claimed as the cause of this anemia, “no activity of the bone marrow.”

Ehrlich's profound knowledge of the chemical procedures used in the synthesis of organic dyes led him to find a special test in urine, the so-called diazo reaction. Of much farther reaching importance was Ehrlich's wide experience with organic dye products for developing staining methods to recognize and to identify the recently discovered bacteria. He introduced methylene blue for this purpose and recommended this dye to his friend, A. Neisser, for use in Neisser's successful search for the organism that causes gonorrhea.

On March 24, 1882, Robert Koch had reported before the Physiological Society in Berlin that he had discovered the bacillus that caused tuberculosis, which he called the “tubercle bacillus.” Less than six weeks later, on May 1, 1882, Ehrlich demonstrated before the Society of Internal Medicine in Berlin his method of staining and identifying Koch's tubercle bacillus by means of its acid-fastness, which Ehrlich had discovered. Ehrlich's method for staining the tubercle bacillus, described in 1882, is practically the same used everywhere today. Robert Koch gave greatest credit to Paul Ehrlich: “It is due to Ehrlich's staining method for finding the presence of the tubercle bacilli that the search for tubercle bacilli in the sputum was universally adopted. Without Ehrlich's method but just a very few research workers may have been able to study the tubercle bacillus.” Thus wrote Robert Koch in 1883.

From the Department of Pediatrics, Northwestern University Medical School, and the Children's Memorial Hospital. Dr. Hermann Pinkus, Wayne University College of Medicine, Detroit, furnished reprints, abstracts, and a memoir concerning Paul Ehrlich.

While Ehrlich intensively searched for tubercle bacilli in the various clinical forms of tuberculosis, he fell seriously ill in 1888. As tubercle bacilli were found in his own sputum, he had to interrupt all his activities. Accompanied and guarded by his wife, Ehrlich went to Egypt for nearly two years for rest and recreation. In 1890, Ehrlich returned fully recovered to Berlin. During this period of relaxation Ehrlich's genius had conceived new ideas. His interest was now attracted by problems of immunity. His investigations were started with methods not applied before. Ehrlich did not use substances of bacterial origin but used instead well-characterized toxic protein products of higher plants, such as ricin and abrin. He showed how animals could be immunized by injection of increasing doses of these toxic substances. He devised methods to determine quantitatively the degree of immunity and the amount of antitoxins present in the blood or serum of the immunized animals. He showed that immunized nursing mice are able to transfer their specific immunity to their offspring but that no immunity can be transferred from immunized father animals. While fascinating from a biological point of view, these studies appeared to the medical profession to be without any practical interest. Few suspected that the results of Ehrlich's "theoretical" studies shortly would revolutionize their therapeutic activities and help them to save many of their patients.

In 1892, Emil von Behring had succeeded in immunizing horses against diphtheria with diphtheria toxin and in producing a completely new type of remedy, a horse serum containing diphtheria antitoxin. However, Behring recognized that the degree of antitoxic efficacy of his products could not be controlled. Before it would be possible to use this new product for the treatment of diphtheria in human beings, it was imperative to find some way to measure the curative potency of the various serums obtained from immunized horses. At this critical moment, Behring sought the advice and the cooperation of Paul Ehrlich.

On the basis of his experience, Ehrlich with his collaborators, Kolle and von Wassermann, developed procedures of obtaining potent antitoxic serums. Ehrlich devised exactly defined units, which he called I. U. (immunization units), for the determination of the content of antitoxins, and he established the fundamental methods of standardizing antitoxin in these immunization units, which were accepted in all civilized countries. Finally, the dose of antitoxin required for the treatment and for prophylaxis of diphtheria was determined in Ehrlich's immunization units. The introduction of diphtheria antitoxin, a scientifically standardized remedy against a dreadful disease, had an enormous impact on medical and especially on pediatric practice. The demand for this unique product rose enormously in Europe, America, and other continents.

In 1896, the Prussian government erected in Steglitz, then a suburb of Berlin, a new institution called "Royal Institute for Standardization and Investigation of Antitoxic Sera." The 42-year-old extraordinary professor of internal medicine at the University of Berlin, Paul Ehrlich, was made the director of this institute and was given the title *Geheimer Medizinalrat* (Privy Medical

Counsel). Here, Ehrlich completed his outstanding monograph on the "Standardization of Diphtheria Antitoxin." He also stipulated the two fundamental principles of immunology: 1. Toxins are strictly specific. 2. Toxins introduced into the animal organism cause the production of equally specific antitoxins, far in excess of the amount required to neutralize the amount of toxin introduced.

To illustrate the reaction between toxins and the body cells and between toxins and antitoxins, Ehrlich developed his much-discussed "side chain theory." According to this theory, each toxin molecule has two groups, the toxophore group that carries the toxic action and the haptophore group that fits into a receptor group of the cell. When the receptor groups of a cell are filled with haptophore groups, the cell is stimulated to produce new receptor groups; according to the law of hyper-regeneration, these new receptor groups are produced in excessive numbers and therefore are released from the cell into the circulation, where they act as antibodies. During these studies Ehrlich made the observation that, after certain procedures, toxins in solutions could lose their toxophore groups but retain their haptophore groups. Ehrlich called these derivatives of the original toxins "toxoids." He emphasized that these toxoids had lost their toxicity but were still able to stimulate the production of antitoxins. He showed how it is possible to transform solutions of toxins into solutions of the corresponding toxoids, and he recommended these toxoids for the purpose of immunizations. It was a quarter of a century and later before the fundamental value of Ehrlich's "toxoids" finally was recognized and the use of toxoids for immunization against diphtheria and tetanus became a universally accepted procedure.

While an increasing number of specific antitoxins were used with great enthusiasm all over the world, Paul Ehrlich recognized that immunotherapy had its definite limitations. It was not possible at that time to prepare antitoxic products against the protozoa, such as the *Plasmodium malariae*, the trypanosomes, spirochetes, and spirillas, nor against the newly discovered filtrable viruses. Ehrlich felt that, in the search to combat these parasites, he had to return to his old trail, to substances that through their chemical structure had a specific affinity to the parasites and were, in Ehrlich's nomenclature, "parasitotrop." His new slogan was "We must learn to aim chemically!"

Toward the end of the 19th century, larger facilities were planned for Ehrlich's work, to be erected in Frankfurt am Main. According to Ehrlich's suggestions, this new institution was built as the "Royal Institute for Experimental Therapy." The examination and standardization of the antitoxins was confined to one department; the greater part of the laboratories was devoted to the search for chemical products suitable for curing infectious diseases. To indicate that this was an entirely new way, different from the methods pharmacology had used up to this time, Ehrlich coined the term "chemotherapy." The best definition of the principles of chemotherapy is given in Ehrlich's own words: "To be successful in chemotherapy we must search for substances which are fitted to annihilate the invading parasites with the least possible damage to the host organism."

For his chemotherapeutic studies Ehrlich then resorted to experimental infections with trypanosomes and spirochetes. These parasites were transmitted to large series of mice, rats, rabbits, and other laboratory animals to test the curative action of any number of chemotherapeutic agents. As such, Ehrlich chose at first his beloved aniline dyes but soon turned more and more to organic compounds of arsenic, which were systematically synthesized according to his designs. The series of animals and the number of preparations tested rose to gigantic figures. His staff of co-workers grew steadily, especially after 1906 when a second institution, the "Georg Speyer House," was built adjacent to the institute. The 606th arsenical compound, arsphenamine (Salvarsan), proved to be a remedy that gave therapeutic results far exceeding those of any drug ever used before in the treatment of syphilis and several tropical diseases. The discovery of arsphenamine in 1910 was regarded as an unprecedented triumph of chemotherapeutic research. Ehrlich was overloaded with honors and decorations.

At the 17th International Congress of Medicine held in London in 1913, Ehrlich gave a summarizing address on chemotherapy. With great satisfaction he told how in Surinam, Dutch Guiana, a hospital for the treatment of 300 patients suffering from frambesia (yaws) had to be closed because this disease, caused by *Spirochaeta pertenue*, a relative of *Spirochaeta pallida*, could now be successfully cured after one injection of arsphenamine. When arsphenamine had been replaced by the easier-to-handle neoarsphenamine (Neosalvarsan), the treatment of syphilis with this drug was generally introduced in several European countries and systematically controlled. Here the incidence of syphilis declined progressively, and, by the middle of the 1930's, congenital syphilis in infants had become almost unknown until the population shifts during World War II brought occasional reappearances.

As important as these therapeutic results appeared at their time, the inspiration that Paul Ehrlich gave to the further development of research and therapy was much farther reaching and longer lasting. His fascinating personality and the unique facilities in both institutions under his direction attracted numerous scientists from many countries. From the United States may be mentioned these men: Professor Herter from New York; Reid Hunt from Harvard, who was Ehrlich's assistant for two years; and William H. Welch, the great reformer of medical education in this country, from Johns Hopkins. A wider part of the medical profession was stimulated by the numerous lectures that Ehrlich was invited to give: the Croonian and the Harben Lectures in England, and the Herter Lectures in New York and Baltimore, followed by lectures in Washington and Chicago. He addressed congresses in Paris, Brussels, and London. In December, 1908, in Stockholm, after being awarded the Nobel Prize, Ehrlich gave an acceptance speech entitled "Partial Functions of the Cell."

Many of the ideas that Ehrlich developed and followed experimentally from 1904 to 1914 concerned the same problems that today, after more than 40 years, form the center of research and interest in chemotherapy. Early Ehrlich recognized and showed experimentally the

dangers of too sudden and too forceful destruction of the parasites because of the toxic products that may be liberated. He emphasized that it is fully sufficient for his "therapia sterilisans magna" to make "each individual parasite unable to reproduce." An ideal chemotherapeutic agent, according to Ehrlich, prevents the multiplication of the parasites. Today we have learned that the action of our best sulfonamides and antibiotics is bacteriostatic and not bactericidal.

In several instances Ehrlich recommended his "combination therapy," the simultaneous application of several chemotherapeutic agents with an entirely different chemical structure and therefore with different "chemoceptors" to attack the parasites from various sides. Ehrlich showed experimentally that in such a combination the toxic side-effects to the host are simultaneously reduced. Again at the International Congress in London in 1913, Ehrlich reported the great success that was achieved by using a combination of arsphenamine with acriflavine (Trypaflavine) and *o*-chlororosaniline (Tryparosan) for the treatment of trypanosomiasis in the Congo region of Africa. Today the same principle is applied in the chemotherapeutic treatment of tuberculosis. Here small doses of the somewhat toxic streptomycin are combined with *p*-aminobenzoic acid (PABA) and isoniazid products.

Ehrlich's greatest concern was the problem of drug-fastness. He recognized as the most frequent cause of drug-fastness treatment with doses that are nearly but not fully sterilizing. He emphasized again and again the dangers of under-treatment. He reported on a strain of arsenic-fast trypanosomes, which, in his laboratory during three years, was transmitted from mice to mice in 400 passages, and the last strain was still arsenic-fast. Ehrlich found that strains from cases in which relapses occurred were not infrequently fast to the drug that had been used for treatment previously. Drug-fastness is mostly limited to one type of drug, but, by prolonged and alternated under-treatment with three different trypanocidal agents, Ehrlich was able to produce a strain of trypanosomes fast to all three chemotherapeutic drugs. It appears that Ehrlich, 40 years ago, because of his extensive studies, was more aware of the dangers of drug-fastness than we realize today.

At Ehrlich's 60th birthday, March 14, 1914, 37 scientists published, as *Festschrift*, a monumental volume of 668 pages entitled "Paul Ehrlich, Eine Darstellung seines wissenschaftlichen Wirkens" (a description of his scientific achievements). Less than five months later World War I broke out. All research was completely disrupted. The man whose endeavor through all his life had been to alleviate human suffering felt his ideals to be wrecked and ruined. Fate spared him still greater disappointments. Paul Ehrlich died on Aug. 20, 1915. His mortal remains were interred in the Jewish Cemetery of Frankfurt, but the results of his genius have survived. During the first 20 years after his death, chemotherapeutic research produced new and improved remedies for malaria, sleeping sickness, and other tropical diseases, in addition to those of minor importance. The world-moving success came when Gerhard Domagk, following orthodoxically the trail shown by the great

pioneer, combined Ehrlich's favored azo dyes with the amide of sulfanilic acid, which had been the model for Ehrlich's arsanilic acid. Domagk's product Prontosil (2,4-diaminoazobenzene-4'-sulfonamide) proved to be the first chemotherapeutic agent of high potency against many of the bacteria that cause the most frequent infectious diseases in children. A disagreeable side-effect of Prontosil, the discoloration of the skin, was removed after Fournau and his group at the Institute Pasteur in Paris had shown that the azo dye component was not absolutely necessary for the therapeutic effect. Prontosil album (sulfanilamide) was introduced and became the mother substance of the numerous sulfonamide drugs synthesized in the following years, the amount now numbering nearly 5,000.

What role Paul Ehrlich's ideas played in the development of penicillin, the first antibiotic, was recently revealed by the very best informed person. In 1902, a young British physiologist, Dr. Henry Hallet Dale, went to Frankfurt and worked with Paul Ehrlich for two years. Ehrlich took a great liking to this gifted scholar

who later became one of Britain's most prominent scientists, was awarded the Nobel prize, and became Sir Henry Dale. As director of the British National Institute for Medical Research, he was informed of each and every step that led to the development of penicillin. On the basis of his experience, Sir Henry Dale in 1949 wrote as follows: "In 1935 Domagk's discovery of the action of 'Prontosil' opened the way to the series of the Sulphanilamide derivatives; and the revolutionary improvements which these effected in the treatment of a number of common infections, played its part in the decision of Florey and his team to examine anew the chemotherapeutic possibilities of the half-forgotten Penicillin, which Fleming had found ten years before. And the new enterprise by the marvelous success of Penicillin has now led to the discovery of Streptomycin, and others are already in sight. But the central idea of experimental chemotherapy, and the initial impulse to its triumphant march forward, came from Paul Ehrlich."

3837 Broadway (13).

TREATMENT OF URINARY TRACT INFECTION

Dean Parker, M.D., Seattle

Urinary tract infections are second in frequency only to infectious processes of the upper respiratory tract.¹ Because of their frequency they are often dismissed as minor problems and may be treated in a rather haphazard manner, but this attitude may lead to serious difficulty and aid in establishing chronic infections with permanent and irreparable renal damage. Contributing to this attitude has been the advent of the chemotherapeutic and antibiotic drugs, which, after a preliminary course of therapy, may give relief of symptoms with striking and immediate results. In any given case, general care and good urologic management will be of greater benefit than any chemotherapeutic treatment. Womack and his co-workers have stated that age and systemic factors not only predispose patients to urinary infection but also militate against optimum beneficial results.² To take the greatest advantage of the recent advances in the use of chemotherapeutic agents in urology, one should consider these important factors³: (1) the suitability of the patients for treatment, (2) the bacteria involved in the infectious process, and (3) the agent or agents best suited for both the patient and the bacteria present.

SELECTION OF PATIENTS FOR UROLOGIC STUDY

When the patient is seen routinely by his physician in the office, the examination may reveal signs or symptoms of urinary tract infection by means of either the history or

the physical findings. Certainly all of these patients do not require complete urologic study; neither should they all be placed immediately on a chemotherapeutic regimen without further study. Those patients in whom physical findings suggest no pathological condition of the urinary tract, in whom no abnormalities are seen on a flat film of the kidney, ureter, and bladder, and in whom a simple, primary, acute infection exists caused by only one organism are the patients who are entitled to immediate treatment with one of the chemotherapeutic agents, without further urologic study. Those patients, however, who have had recurrent or chronic infections, in whom smear or culture tests reveal mixed organisms, in whom there are abnormalities of the lower urinary tract, prostate, genitals, renal mass, or in whom calcified areas that might be in the upper urogenital tract appear on the flat film are the ones who should have a complete urologic examination prior to institution of therapy. It is well known that, in the presence of abnormality of either the upper or lower urinary tract, chemotherapy is ineffective and may lead only to making the organisms resistant to the agent that, at a later date, might prove most effective. Any such urinary tract abnormality must first be corrected before more than a temporary effect can result from medication. In those cases in which it is felt that further urologic examination is necessary, the diagnostic procedure should be followed in an orderly manner, step by step, either to a satisfactory conclusion in diagnosis or to a complete urologic study with all its components. In those cases of simple acute infection in which antibiotic therapy has been instituted, if there is no immediate response, further urologic study is indicated.

Read before the Section on Urology at the 102nd Annual Meeting of the American Medical Association, New York, June 4, 1953.

CAUSATIVE ORGANISM

After ruling out or correcting fundamental abnormalities of the urinary tract, one must consider the type and degree of infection. It is important to obtain a sterile voided specimen from a man and a catheterized specimen from a woman during an acute attack. The centrifuged specimen should be examined for bacterial and cellular content. The question of whether to prepare a smear or a culture is sometimes difficult to decide. The smear has certain advantages in that it gives an immediate result and it establishes to some degree the number of organisms involved. The culture, on the other hand, although time consuming and somewhat more expensive, is advantageous in that it insures absolute identification of the organism, and the plated culture permits the use of sensitivity studies for the organism found. The culture of the organism is necessary for the purposes of correlation and for the treatment of complicated cases. Relatively few kinds of organisms are observed in cases of urinary tract infection. Simple infections of the acute variety are usually due to *Escherichia coli* or *Aerobacter aerogenes* and a *Staphylococcus* (*Micrococcus*); after instrumentation or surgery, *Proteus* and *Pseudomonas* organisms may be found, in addition, among the rods, and *Streptococcus fecalis* or enterococcus organisms among the cocci.⁴ It seems obvious, therefore, that, for the routine clinical application, the gram stain is of considerable value in the diagnosis of the acute simple urinary tract infection. In the complicated or recurrent or chronic case, culture and sensitivity studies should be done. There are three main reasons for using the sensitivity studies⁵: (1) chronic or recurrent infection, (2) infection resistant to previous antibiotic therapy, or (3) severe and fulminating infection.

THE ANTIBACTERIAL AGENT

For the intelligent use of the antibacterial agents in the treatment of urinary tract infection, one should consider certain principles in their action upon the living organism. The first factor to be remembered is that the action of the antibacterial agent is on the organism and not on the host. It affects the organism by interfering with certain metabolic activities of the growing cell. Most antibiotic agents are bacteriostatic in low concentrations and bactericidal in high concentrations. They differ from antiseptics in that they interfere with growing cellular metabolism rather than destroy the cell wall of both the bacteria and the host. The chemotherapeutic ratio is determined by the number of metabolic processes the agent inhibits. The second factor to be considered in the use of antibacterial agents is that the resistance of the organism to antibiotic agents may limit their effectiveness. Organisms may have natural immunity to the drug or may have acquired immunity by previous exposure. It is for this reason that it is important to have new drugs at hand, since with time and use a once-effective agent may become almost useless. This is now the case with penicillin in some instances, and the development of erythromycin has been extremely timely.

A third factor that must be considered in the use of these drugs is that toxicity may limit the dosage used. The principal limiting factor in the use of chemotherapeutic agents is toxicity, caused either by the dose relationship

or by the sensitivity of the host. Many of the toxic reactions for the sulfonamide drugs were due to dose relationship, while all those from penicillin result from sensitivity of the host, with no relationship to the dosage administered. O'Connor⁵ repeats an old saying, "One man's food is another man's poison," which is particularly true in this regard. Raper reports that probably 300 antibiotics have been isolated. Most are too toxic for general use, and only six or eight have reached clinical maturity. A fourth factor in considering the agent to be used is the amount of absorption by blood and tissues and excretion. Because of the relationship of the concentration to the effectiveness of the agent, this consideration is important. Consideration also should be given as to whether the process is an interstitial type of infection or a topical or mucous membrane infection. On this basis one might seek a high tissue absorption level or a high excretion level, depending on the nature of the infectious process.

Percentage distribution of 332 micro-organisms isolated from urinary tract infections in 325 patients (adapted from Rhoads et al.).

In treating interstitial infections, intensive and protracted treatment of the patient is often necessary and a thorough follow-up with urine cultures should be made despite cessation of symptoms. As an example, a child with chills, fever, and pyuria is seen by the pediatrician; treatment results in marked clinical improvement. The patient may next be seen with "honeymoon pyelitis" by the gynecologist, and brief antibiotic treatment results in an apparent cure. At 20 she is seen in the third trimester of pregnancy with signs of urinary tract disease with or without toxemia. At 30, when she again notices signs of urinary tract infection, she is seen by a urologist who finds essentially normal pyelograms but intrinsic renal infection. He starts a course of treatment with such marked improvement that she fails to return for follow-up treatment. This patient at 35 begins to feel weak and tired and

again has a urinary tract flare-up. She is then found to have irreversible renal damage and uremia with chronic pyelonephritis. The prognosis is poor. This woman will require continued palliative medical care. This type of story, treatment, and result can in many cases be avoided by prolonged, intensive, and varied treatment and follow-up studies.^{5a}

The last and fifth factor to be considered in the choice of an antibiotic agent is the effective drug combination. It may have a synergistic action, as in the case of streptomycin and one of the sulfonamide drugs, or an inhibiting effect such as reported with streptomycin and chloramphenicol⁶ (Chloromycetin) in certain types of infection in which the combination is less effective than either drug alone.

In considering the inhibiting effect of one drug upon another, one also should consider inhibition of organisms by other organisms. This established bacterial relationship may be abolished by antibiotics. With the elimination of one group of organisms, an organism that was not pathogenic previously with normal flora may become pathogenic and cause infection.⁷ An example of this is seen with the use of any of the broad spectrum antibiotics in sterilization of the intestine prior to surgery. The result may be an overwhelming staphylococcal enteritis, several cases of which have been fatal. The following combinations of drugs can be used in infectious processes due to each one of the organisms listed⁸: (1) *Esch. coli*, chlorotetracycline (Aureomycin), oxytetracycline (Terramycin), or chloramphenicol plus sulfisoxazole (Gantrisin); (2) *Str. fecalis*, chlortetracycline, oxytetracycline, or chloramphenicol plus sulfisoxazole or penicillin; (3) *Pseudomonas aeruginosa*, oxytetracycline or streptomycin plus sulfisoxazole; (4) *Proteus* organisms, chloramphenicol plus sulfisoxazole; (5) *A. aerogenes*, oxytetracycline, chloramphenicol, or streptomycin plus sulfisoxazole; (6) micrococci, chlortetracycline plus penicillin; (7) *Str. hemolyticus*, penicillin plus sulfisoxazole; and (8) *Klebsiella pneumoniae*, chloramphenicol or streptomycin. In review of these factors, many variables are seen that might influence the effectiveness of an agent.

TOPICAL USE OF ANTIBIOTICS

While it seems rational to depend upon tissue and urinary concentrations of antibiotics in eradication of infectious disease, there does seem to be a place in the urologic armamentarium for the topical use of these agents. Certain chronic infections of the urethra or bladder causing pathological conditions that cannot be corrected, may show marked improvement with therapy with these drugs. In wound infections in which the organism is resistant to nontoxic agents, a more toxic agent may prove beneficial as a topical medication. I am thinking here of the use of 1% to 5% solutions of the broad spectrum antibiotics in nonspecific anterior urethritis and the use of polymyxin in 1% solution in kidney and bladder infections by *Ps. aeruginosa* or the use of bacitracin in wound infections with resistant organisms.

CONCLUSIONS

There has been a tendency to disregard well-established, somewhat standardized aspects of the treatment of urinary tract infections because of rather miraculous

progress in the chemotherapeutic treatment of these diseases. Proper diagnosis, sound surgical principles, and elimination of other foci of infection plus sound supportive medical measures are still of primary importance in the treatment of these patients. Only on this basis can we expect maximum and permanent eradication of infection with careful and judicious use of any and all of the available and indicated chemotherapeutic drugs. To complete bacteriological knowledge, some trial-and-error use of the drugs may still be required before cure is attained, but new drugs are important and should be accepted for use if they are less favorable to resistance, less toxic to the patient, and more potent either in themselves or in combination with other agents than existing antibiotics or other agents.⁹ Finally, the most important factors in the treatment of urinary infection are proper consideration of etiology and diagnosis, sound urologic treatment of any pathological condition discovered, good general medical management, eradication of other foci of infection,¹⁰ and bacteriological choice of the proper drug. It is then necessary to avoid toxicity, treat fully, and follow the patient for recurrence before eradication is presumed.

Polymyxin B.—[The Drug] was used to treat ambulatory, asymptomatic and symptomatic individuals found to have *Pseudomonas aeruginosa* in the gastrointestinal tract. In the control group of asymptomatic carriers, about half of the cases were spontaneously free of the organism in the follow-up studies 25 and 30 days later. One hundred fifty milligrams of the drug were given orally every eight hours for seven days to the experimental group. After five days, all the stools were negative for pseudomonas. Stool cultures were repeated in 23 cases, 25 and 30 days after the drug had been started. At this time, all but one were negative for pseudomonas. About half of the subjects receiving the drug had mild abdominal cramps or mild diarrhea or both between the first and third days of drug administration, and these lasted from a few hours to two days. They disappeared in each instance in spite of continuation of therapy and without administration of other drugs. Polymyxin B should be considered promptly as one of the control measures in any outbreak of diarrhea in a newborn nursery where pseudomonas is found as the most likely pathogen. Its use may also be considered as a prophylactic measure when personnel are found to harbor this organism. Oral polymyxin B is very effective in eliminating *P. aeruginosa* when it is present in the gastrointestinal tract either in carriers or in active infections.—G. Y. Mills, M.D., and B. M. Kagan, M.D., Effect of Oral Polymyxin B on *Pseudomonas Aeruginosa* in the Gastrointestinal Tract, *Annals of Internal Medicine*, January, 1954.

CONTROL OF URINARY INCONTINENCE IN PATIENTS WITH MULTIPLE SCLEROSIS

S. Richard Muellner, M.D., Boston

It has been estimated that there are several hundred thousand persons in the United States who have multiple sclerosis. Recent surveys have shown that there are more than 4,500 cases of multiple sclerosis in the New England states alone, and of these 2,000 exist in Massachusetts.¹ About one-third of the patients who have multiple sclerosis have distressing urinary symptoms. These symptoms consist of frequency, nocturia, urgency, incontinence, and enuresis. In the past, very little could be done to mitigate these symptoms. Therapeutic failure was, in large measure, due to attempts to restore bladder control by drugs that were used to influence the central nervous system lesion of multiple sclerosis.

During the past three years I have had the opportunity to observe 85 patients with multiple sclerosis who in addition had urinary symptoms. The results of this study form the basis of this report and suggested that it was possible to approach the problem from another direction. To be sure, nothing could be done to alter the central nervous system lesion. Would not, however, a better understanding of the pathological physiology of micturition in multiple sclerosis enable one to influence favorably the behavior of the bladder? This shift in emphasis from the central nervous system to the bladder itself proved profitable. Better understanding of the behavior of the bladder in multiple sclerosis made it possible to allay frequency and nocturia and to enhance significantly urinary control.

Space does not permit a detailed review of the normal physiology of micturition and the way in which it is altered in multiple sclerosis.² For voluntary initiation of the urinary stream, however, the coordinated function of the thoracic diaphragm, the abdominal musculature, and especially the levator ani is necessary. Control of the levator ani and the pubococcygeus, which is the anterior portion of the levator ani, is needed to stop the urinary stream and to inhibit the contracting detrusor.

The patient with multiple sclerosis who suffers from urinary incontinence cannot readily contract the levator ani. He is just as awkward in the control of the levator ani as he is in the coordination of his leg muscles, an awkwardness that results in his peculiar gait. The detrusor too can be quite uncoordinated in its contraction and is extraordinarily hyperirritable. Portions of the bladder may contract separately, or the whole organ may go into spasm in response to minor stimuli (fig. 1 through 4). The commonest stimulus to induce an unwanted detrusor contraction is a sudden increase in intra-abdominal pressure that results from efforts such as rising from the recumbent or sitting posture, lifting weights, climbing stairs, and stepping onto or off curbs. These sudden detrusor contractions are responsible for the precipitous urgency and the involuntary micturition in multiple sclerosis. Because he is unable to contract the levator ani quickly, as a normal person can, the patient with multiple sclerosis cannot inhibit the detrusor that then proceeds to empty

the bladder. A clear understanding of these factors that affect micturition in multiple sclerosis makes it possible to control urinary symptoms satisfactorily.

MANAGEMENT

The management of the bladder in multiple sclerosis is based on relatively simple principles. 1. The bladder must be shielded against unnecessary stimuli to reduce urgency. 2. Detrusor hyperirritability must be reduced to eliminate incontinence. 3. The bladder capacity must be increased to lessen frequency and nocturia.

Clinically, these principles can be translated into the following plan of management. The clinician must become familiar with the patient's pattern of living. This he can readily do by reviewing the patient's activity in a typical day. Since urgency and incontinence are apt to be brought on by efforts that tend to increase intra-abdominal pressure suddenly, the history should bring out which activity is most apt to be followed by sudden urgency or incontinence and ways in which such activities can be circumvented or eliminated. Information on the daily fluid intake is important. For the patient with multiple sclerosis, a large fluid intake is undesirable and needlessly increases urinary frequency. The behavior pattern of the bladder is next ascertained by a simple record, which the patient is asked to keep for a 24 hour period, in which the amount of urine in each micturition and the time of voiding are recorded. The record may show a urinary frequency of 8 to 20 times a day; nocturia of 7 to 8 times; and a voiding volume of 15 to 90 cc. The analysis of this record often shows bouts of frequency during certain hours of the day. This information is helpful in planning drug therapy.

The physical examination of the patient must include a careful rectal examination in which particular attention is paid to the tonicity of the rectal sphincter and to the ability of the patient to contract or relax the levator ani at will. The better the voluntary control of the levator ani, the easier it is, as a rule, to restore nearly normal micturition.

The neurogenic bladder of multiple sclerosis is subject to spontaneous infections. The upper urinary tract, on the contrary, is seldom affected by the disease. Acute and

chronic cystitis constitutes an added powerful stimulus to the hyperirritable bladder. It is, therefore, very important to determine whether the urine is infected. All therapy will fail as long as cystitis persists. Since infections are apt to recur, they must be watched for and treated vigorously with appropriate antibiotics.

The hyperirritability of the bladder can be significantly lowered or completely eliminated for hours at a time by the judicious use of anticholinergic drugs. Of these atropine sulfate is the cheapest and often the best. How much atropine to use and when to use it must be determined for each patient. Moreover, since multiple sclerosis is subject to remissions and exacerbations, the dosage schedule has to be adjusted according to the course of the disease. Successful control of urgency and incontinence does not mean that the patient must receive continuous anticholinergic medication. To do so may cause urinary retention

Fig. 1.—Cystogram showing hyperirritability of detrusor in patient with multiple sclerosis; note spasm of bladder from mere contact with catheter.

or relax the detrusor to the point where micturition becomes difficult or inefficient. Conversely, rule of thumb administration of the drug at arbitrarily chosen regular intervals may fail to produce urinary continence at the time when the patient most needs it. Anticholinergic drugs do not "cure" the abnormal bladder in multiple sclerosis. They can be used very successfully, however, to produce the right effect at the right time; in other words, one uses them not like an iron pill three times a day after meals but like a cocktail that is useful for a desired effect at a particular moment.

It is here that the micturition record mentioned above and the pattern-of-living information can be a very useful guide in the spacing of the medication. A tablet containing 0.4 mg. (1/150 grain) of atropine sulfate taken by mouth may abolish vesical irritability for from two to four hours. If, in the morning, the patient has a good deal of frequency and urgency that interferes with his activity, the tablet can be given one-half to three-quarters of an

hour before arising. Some patients need it only for periods of the midafternoon or evening. It is easy to teach a patient to note the length of time it takes for the drug to take effect and the duration of this effect. He soon learns to take the drug in a way that will achieve urinary con-

Fig. 2.—Cystogram obtained during excretory urography; Arrows point to deep folds that are results of contractions of bladder muscle.

tinence for the desired period of time. It is seldom necessary to use more than three to five tablets a day. Some patients do not tolerate atropine well because of excessive dryness of the mouth or visual disturbances. (Preexisting blurred vision may become aggravated.) When this occurs, other anticholinergic drugs may be tried. Bellafoline (containing 0.25 mg. total levorotatory belladonna alka-

Fig. 3.—Retrograde cystogram in patient with multiple sclerosis showing irregularly contracting detrusor with upward projection of bladder dome and pseudodiverticula.

loids per tablet) is a satisfactory substitute for atropine and is less apt to cause visual disturbances or dryness of the mouth. In general, it is a more comfortable drug for the patient than atropine, although it is not quite as powerful, tablet for tablet, as the latter is in allaying detrusor

hyperirritability. Another drug that can be quite useful if neither atropine nor Bellafoline is tolerated is Octin (containing 0.12 gm. [2 grains] of methylisoactenylamine per tablet). Octin also is not likely to cause visual disturbances or dryness of the mouth. Occasionally it will

Fig. 4.—A, small spastically contracted bladder despite gentle filling at low pressure; B, same bladder with larger capacity and smooth bladder wall 30 minutes after administration of atropine.

brilliantly decrease bladder irritability. Some patients, however, experience peculiar "sensations" that they cannot describe accurately and that cause them to refuse to take the drug. Methantheline (Banthine)³ has also been reported to have a powerful effect on the bladder and it undoubtedly has. It has been difficult, however, to

achieve an even effect on bladder irritability with methantheline. It either relaxes the bladder too much or not enough. The newer derivative of methantheline, propantheline (Pro-Banthine) bromide, was not given to any of the patients.

Except in the final stages of the disease when an atonic overdistended bladder with overflow incontinence is commoner is it ever necessary to treat the urinary incontinence by means of an indwelling catheter. In some patients, the whole urinary picture may be complicated by coexisting urologic disease, such as an obstructing prostate in a man or urinary stress incontinence in a woman. The management of these problems, however, is not within the scope of this paper.

SUMMARY AND CONCLUSIONS

There are more than 4,500 cases of multiple sclerosis in the New England area; of these, 2,000 exist in Massachusetts. One-third of these patients suffer from distressing urinary symptoms, most of which can be successfully controlled by a plan of management in which the patient's pattern of living and the condition and behavior of his bladder are carefully considered. Anticholinergic drugs play an important part in the therapeutic plan, if they are used on an individual basis with due consideration of the various factors discussed.

NOCTURNAL AND INSULIN GASTRIC SECRETION

William H. Olson, M.D.

and

Anna B. Bridgwater, M.S., Chicago

This study on normal inmates and inmates with duodenal ulcer in a penitentiary was undertaken to settle the question of whether an ulcer patient secretes more gastric juice than a normal person. Previous studies by other investigators have demonstrated that most duodenal ulcer patients secrete a higher nocturnal volume of gastric juice with a higher acidity than normal persons. Chalfen, in 1928, reported that normal subjects do not secrete acid during the night, in contradistinction to high acid secretion in ulcer patients. Winkelstein, in 1935, confirmed these findings; 45% of his normal subjects did not reveal any free hydrochloric acid. On the other hand, Sandweiss and associates,¹ in 1946, and Brown and co-workers,² in 1952, found no significant difference between the nocturnal secretion of normal persons and ulcer patients, when no retention was present in the latter group. A historical review of the literature on gastric secretion in normal persons and ulcer patients was presented by Sandweiss and associates³ and a critical evaluation of nocturnal secretion studies by Ivy and others.⁴

In our series, 97 secretion studies were made on 66 subjects—53 on 26 ulcer patients and 44 on 40 normal

subjects. Studies in which subjects withdrew before the tests were completed are not included. A few tests were invalidated by technical difficulties, such as obstruction of the Levin tube or its propulsion into the duodenum as determined by fluoroscopy.

PROCEDURE

The study was performed over a period of two years. All patients were men whose average age was 40 years, the variation being from 28 to 57 years. The majority of

2. Brown, G. M.; Purchase, E. C. R., and Bresnahan, T. J.: Nocturnal Gastric Contents in Duodenal Ulcer and Non-Ulcer Dyspepsia: Studies of Volume, Acidity and Peptic Activity, *Gastroenterology* 21: 331, 1952.

ulcer patients were studied from November, 1951, to May, 1952, and the normal subjects during the same months in 1952 and 1953. Thus, possible seasonal effects on gastric secretion were largely eliminated. The ulcer patients were selected carefully from a group of 156 men with a previous diagnosis of duodenal ulcer on the basis of the following four criteria: (a) the presence of typical epigastric distress with nocturnal pain; (b) distinct right upper quadrant point tenderness; (c) a definite ulcer crater shown by fluoroscopy and x-ray study; and (d) no other symptoms or disease.

The normal subjects were selected from a group of volunteers who had been imprisoned for a period of two or more years. Their medical history in the institution was checked, and the drug card was particularly examined to determine whether at any time they obtained antacids, Sippy powders, or alkali for treatment of any type of gastric distress. Any normal subject was rejected for the following reasons: (a) history of self-medication of antacids; (b) history of hospitalization for gastrointestinal disturbance, and (c) the presence of any type of disease. All were given physical examinations and, after the secretion studies, complete gastrointestinal x-ray

control period samples were collected for the Hollander insulin test. Then 15 units of insulin were given intravenously, and the samples of gastric juice were collected every 15 minutes for the following two hours. Blood sugar was determined by the method of Nelson.

RESULTS

All secretion experiments are summarized in table 1 and in the figure. In 34 normal subjects who secreted free acid, the volume of 12 hour nocturnal secretion ranged from 500 to 1,915 ml., with an average of 1,021 ml. The milliequivalents of total free hydrochloric acid secreted during this period varied from 13.5 to 105, with an average of 51. The Hollander insulin test showed a range from 89 to 491 ml. of gastric juice, with an average of 245 ml.; the milliequivalents of free hydrochloric acid ranged from 1.7 to 46.8, with an average of 17.9.

The results of 50 tests performed on 26 ulcer patients showed, in the 12 hour nocturnal secretion, a range from 210 to 2,025 ml., with an average of 945 ml. The milliequivalents of free hydrochloric acid ranged from 6.6 to 131, with an average of 49.6. The two hour Hollander insulin test produced a secretion in the ulcer patients with

series were performed. In this group, one patient with silent ulcer and one with prolapse of gastric mucosa were found; they were not included in the normal group.

For the study and work-up, all subjects were hospitalized for a period of at least two days and were fed a soft diet including eggs. Before the secretion tests, food and water were withheld for four and one-half hours. For the nocturnal secretion test, a large Levin tube was passed through the nose and the stomach was emptied for a period of 30 minutes before beginning the collection of the 12 hour secretion. Constant suction was employed by means of a Gomco suction pump. An attendant was assigned to each subject throughout the night for checking the Levin tubes at hourly intervals or more frequently for possible obstruction. The gastric juice was titrated for free and total acidity, and the pepsin content was determined by the method of Bucher, Grossman, and Ivy. A 12 hour urine specimen was collected during the period of nocturnal gastric secretion in 17 ulcer patients and 32 normal subjects, and uropepsin was estimated by a modification of Anson's method. A uropepsin unit was defined as that amount of enzyme that would release 1 mEq. $\times 10^{-4}$ of tyrosine in a 10 minute incubation period at 37°C. The following morning the Levin tubes were disconnected from the constant suction and two 15 minute

a range from 53 to 411 ml., with an average of 222 ml. The milliequivalents of free hydrochloric acid ranged from 2 to 32, with an average of 14.8.

Whenever a subject, whether normal or with a duodenal ulcer, showed no free acid in the 12 hour nocturnal secretion or in the insulin test, the test was not included in the averages in table 1. There were three duodenal ulcer patients without free acid in the 12 hour nocturnal secretion, but repeated tests showed a high secretion rate with high acidity, the total milliequivalents of free hydrochloric acid being 48, 56.7, and 29.5. Table 2 shows the results in 10 normal subjects who showed no free acid during a 12 hour nocturnal secretion test. The secretion studies were repeated on four of the subjects and showed values of 29 to 46 mEq. of hydrochloric acid. At this point of the study, it was decided to determine the amylase activity of the gastric contents whenever no free acid was present. Somogyi's amylase method was used, the gastric juice being diluted according to Free and Myers. By this means, we expected to demonstrate neutralization of acidity by regurgitation of duodenal fluids into the stomach. The normal subjects, patients 3 and 4 in table 2, with no free acid, showed 320 and 650 amylase units per milliliter, respectively. On repetition of the tests, free acid was present, but no amylase activity. The remaining six normal subjects showed similar results, namely amylase activity ranging from 440 to 1,530 units per milliliter of gastric juice in the absence of free acidity. We have interpreted this to mean that, in those tests

where no free acid was present, a significant amount of regurgitation of duodenal contents occurred, enough to neutralize whatever free acid was secreted. For this reason we have felt justified in not including in table 1 any nocturnal or insulin secretion test that showed no free acid.

In table 3 the results of the 12 hour nocturnal secretion tests were regrouped according to rate of secretion of total milliequivalents of free hydrochloric acid. In group 1, with free acidity present in all tests, the averages of the normal subjects and of the duodenal ulcer patients were practically identical. However, when all tests, irrespective of presence or absence of free acid, were averaged (group 3) there was a significant difference between normal subjects and duodenal ulcer patients, namely, 39 and 47 mEq. of hydrochloric acid respectively. In group 4, values for those with a high secretion, an output of 60 mEq. and above, showed only a slightly higher average for the ulcer patients as compared to the normal subjects. Yet, in group 6 with low secretion, with 0 to 20 mEq., the duodenal ulcer patients averaged more than twice the milliequivalents of hydrochloric acid than the normal subjects. We could have shown a significant difference also between duodenal ulcer patients and normal subjects, had we compared the results of the high and medium secretion in ulcer patients of group 7 with the

low and medium normal secretion of group 8, the values for the former being 56 and for the latter 28.5 mEq. of total free hydrochloric acid.

The values for uropepsin and pepsin in normal subjects and in ulcer patients, as determined in 12 hour urine and 12 hour gastric juice respectively, are compared in

table 1. In 34 normal subjects, the variation of uropepsin was from 26 to 637 units, with an average of 206 units per hour. The pepsin content of the gastric juice varied from 70 to 290 units, with an average of 168 units per milliliter. In 17 ulcer patients, uropepsin values varied from 23 to 281, with an average of 160 units per hour. The pepsin content of the gastric juice varied from 30 to 275, with an average of 150 units per milliliter.

COMMENT

Comparison of our results with those of other investigators must be limited to those in which continuous aspiration was used for collection of nocturnal secretion. Mears,⁵ in 1943, was the first to employ this method, while Chalfen, Winkelstein, Henning and Norpoth, and others have used intermittent aspiration. Mears⁵ reported that average volume and acidity were higher in 15 patients with duodenal ulcer than in 50 controls. However, his control subjects, as well as those of a number of other investigators, cannot be considered normal, because they were patients who had either chronic cholecystitis or recurrent appendicitis. In comparing our results with those of other investigators, therefore, we have

Comparison of results of nocturnal secretion studies with those reported by other investigators.

selected only those who have performed the study in a manner similar to our method.

In the figure, the values for nocturnal secretion in normal and ulcer patients, as reported by Brown and co-workers,² Sandweiss and associates,³ Levin, Kirsner, and Palmer,⁶ and Dragstedt⁷ are compared with our results. Of these five studies, two showed a significant difference between normal and ulcer patients (Levin, Kirsner, and Palmer⁶ and Dragstedt⁷). Brown and co-workers² and Sandweiss and associates,³ although they used shorter periods of collection, 7 and 10 hours respectively, did not obtain this marked difference, and our results are in agreement with their findings. Our normal subjects however, showed a higher volume and higher acid content than those of all other investigators. The normal subjects of Levin,⁶ Kirsner, and Palmer⁶ secreted 18.6 mEq. of hydrochloric acid, those of Dragstedt⁷ 18 mEq.,

7. Dragstedt, L. R.: Rationale and Technic of Vagotomy, in Sandweiss, D. J., editor: Peptic Ulcer: Clinical Aspects, Diagnosis, and Management, Philadelphia, W. B. Saunders Company, 1951, p. 490.

those of Sandweiss and associates⁸ 17 mEq., and those of Brown and co-workers² 11 mEq., whereas our normal subjects secreted 51 mEq.

In an attempt to find the reasons for the discrepancy between our results and those of Levin, Kirsner, and Palmer and Dragstedt, the results of our nocturnal secretion tests were regrouped according to rate of secretion of total milliequivalents of free hydrochloric acid, as shown in table 3. Group 1 contains those persons who secreted free hydrochloric acid and it is seen that the difference between normal and duodenal ulcer patients was not significant. However, when all tests, i. e., those with and those without secretion of free acid, were averaged in group 3, the duodenal ulcer patients showed a higher rate of secretion of hydrochloric acid, 47 mEq., as compared to 39 mEq. for the normal persons. The tests were then broken down into groups with high secretion, i. e., secretion of 60 mEq. of hydrochloric acid or above; medium secretion, secretion between 20 and 60 mEq.; and low secretion, secretion between 0 and 20 mEq. Our results would have been similar to those of Sandweiss, recalculated for 12 hour periods, if our normal subjects and duodenal ulcer patients had all had low and medium secretion. In normal subjects, Sandweiss and associates³ obtained 17 mEq. during a 7 hour nocturnal period, whereas we obtained 28.5 mEq. during a 12 hour nocturnal period in group 8, with low and medium secretion. In duodenal ulcer patients, Sandweiss and associates³ obtained 22 mEq. for 7 hours, and we obtained 32 mEq. for 12 hours in group 8, with low and medium secretion. On the other hand, we could have shown results in duodenal ulcer patients similar to those of Dragstedt,⁷ if our subjects had been grouped as follows. If all our ulcer subjects had had high and medium secretion, group 7, the average of 42 tests would be 56 mEq. of hydrochloric acid, as compared to 60 mEq. in Dragstedt's series. It would appear, therefore, that the type of patient and the experimental procedure employed would greatly influence the amount of nocturnal gastric acid secretion obtained. As table 2 illustrates, one can obtain almost any average if negative secretion tests (no secretion of free acid) for individual patients are included in a series. It was explained above that second tests yielded high amounts of free acid and that the negative tests were due to regurgitation. Our data indicate that regurgitation and neutralization of gastric acid may occur more frequently in normal subjects than in patients with duodenal ulcer.

It is well known that duodenal ulcer patients are persons under considerable tension. In a study of normal subjects for comparison with duodenal ulcer patients, therefore, it would be necessary to obtain the normal persons from the same environment and to perform the tests under the same conditions. The practice of using hospitalized patients as normal subjects cannot give a

true comparison. Of equal importance is the question of whether a fair comparison can be made by using medical students or hospital personnel as normal subjects when they are familiar with the tests. We feel strongly that normal subjects should be those persons who are in the same environment, under the same tension and stress as the ulcer patient. It is for this reason that we selected the penitentiary for the study of nocturnal secretion.

There are several possible explanations as to why normal prisoners have a higher level of acid secretion than normal persons on the outside. It can be pointed out that a prison environment is far from normal and that all men are under considerable emotional tension, having a great deal of hostility, resentment, fears, and anxiety, all of which are difficult to eliminate in the abnormal environment of a penitentiary. In other words, these men are living under constant stress and this fact may be reflected in the high uropepsin output in the urine. It has been shown by Spiro and others⁸ that administration of corticotropin (ACTH) or cortisone can cause a marked increase in uropepsin output in the urine. Janowitz, Levy, and Hollander⁹ reported normal uropepsin values to be 47 units per hour, whereas we obtained an average of 206 units per hour for the normal prisoner, more than four times the reported normal average; on the other hand, our values for duodenal ulcer patients of 180 units per hour of uropepsin are similar to those of 160 units per hour, reported by Janowitz, Levy, and Hollander.⁹

Concerning the peptic activity of the gastric juice, our findings differ from those of Brown and associates.² They found twice the value of pepsin secretion in the duodenal ulcer patient as compared to normal controls, whereas we observed the same peptic activity in normal subjects and in duodenal ulcer patients.

It has been demonstrated by Gray and others,¹⁰ Zubiran, Kark, and Dragstedt,¹¹ and others that corticotropin and cortisone increase the secretion of gastric juice. Therefore, it can be postulated that, as a result of the chronic stress men are exposed to in a penitentiary, there is a marked increase in adrenal cortical activity due to the stimulation by corticotropin from the pituitary. This results in an increased secretion of a number of adrenal steroid hormones including cortisone. Some of these hormones stimulate the stomach to secrete gastric juice and pepsinogen, producing high volumes of acid gastric juice and a high uropepsin output.

A complete survey of the entire population of the prison, 2,400 men, revealed a high incidence of gastrointestinal complaints. This will be reported in a subsequent paper. We mention this because it is to be expected that, when normal men secrete amounts of gastric juice of such high acidity, there would be a considerable number of such symptoms. Having the physiological evidence, namely, that these normal men secrete so much acid, steps should be taken to alleviate the harmful effects of this hypersecretion. The first step would be to be cognizant of the fact that the men complaining of gastrointestinal symptoms may have justification for their complaints and that adequate medical therapy directed toward correcting the symptoms is necessary. The second factor in combating this hypersecretion in inmates of a penitentiary is to consider drastic changes in diet. There are more suggestions that could be entertained, but we

believe that, to rehabilitate a man successfully, he first must be free of symptoms. A person who has a hyper-secreting stomach and who has no means of neutralizing the acidity would be less amenable to rehabilitation than one who is symptom-free.

We wish to reemphasize that, whenever a person secretes no free acid for 12 hours, this need not represent the true secretory ability of his stomach. Repeated tests (table 2) have shown that, in seven cases in which no free acid was obtained in the first test, the men were able to secrete large amounts of acid in subsequent tests. The finding of a relatively high amylase content in a gastric juice with no free acid suggests that considerable regurgitation of duodenal contents has neutralized the free acid. Earlier investigators, particularly Winkelstein, found a high incidence of absence of free acid in normal subjects, an incidence of 45%, which is higher than reported by others. The evidence that we present here shows quite definitely that the normal stomach may secrete free acid when tests are repeated. For this reason, whenever we obtained results in nocturnal or insulin secretion studies that showed no free acid, they were not included in the averages. Brown and co-workers² suggest, however, that such a procedure does not represent the true character of nocturnal gastric secretion. They state that "gastric contents are the sum of gastric secretion, swallowed saliva and regurgitation of various duodenal contents, and it is misleading to suggest that it is only gastric secretion which is being studied." We agree with this statement, but we want to add that the method

of collecting secretion involves many inaccuracies, the greatest of which may be the collection of a combination of duodenal regurgitation and gastric juice. Hence, the greatest source of error in the procedure may occur when gastric acidity is low or absent; on the other hand, when there is high acidity, we can be more certain of ascertaining accurately the true capacity of the stomach to secrete. The fact that we obtained no difference in the two hour Hollander insulin tests between normal and ulcer patients adds further evidence that there is no great difference between the secretory capacity of the stomach of a normal person and of an ulcer patient.

SUMMARY

Twelve hour nocturnal gastric secretion studies showed that normal men in a penitentiary secrete a larger volume and more acid than normal subjects as reported by others. Comparison of the 12 hour night secretion of normal subjects and of duodenal ulcer patients showed no significant difference in volume and acidity, and the gastric secretory response to the Hollander insulin test showed no significant difference between normal and ulcer patients. The uropepsin concentration in a 12 hour urine specimen was higher in normal men in a penitentiary than in normal men reported on by others. However, uropepsin secretion was the same in the normal and in the ulcer group. The peptic activity of the 12 hour nocturnal gastric secretion was the same in both groups of subjects studied.

VERTEBRAL FRACTURES AS A COMPLICATION OF ELECTROCONVULSIVE THERAPY

Paul A. Dewald, M.D., Norman M. Margolis, M.D.

and

Herbert Weiner, M.D., Rochester, N. Y.

One of the complications of convulsive seizures, regardless of etiology, is compression fracture of the vertebrae. Lehdorff¹ first reported this occurring in tetanus. Reed and Dancy² and Cook and Sands³ found an incidence of 34.2% and 10.4% respectively in groups of patients with idiopathic epilepsy. After the introduction of pentylenetetrazol (Metrazol) shock treatment, Stalker and Wespi were the first of many to report on the incidence of such fractures with this form of therapy. The reported incidence has varied from 0.375% to 47%.⁴ However, in the majority of these papers the number of cases was small, and the design of the studies raised doubts concerning their statistical validity. In the first adequate study of a large series of cases by roentgenograms before and after pentylenetetrazol therapy, Easton and Sommers^{4a} reported an incidence of 26.1% fractures in a series of 800 cases. The study included both men and women of ages ranging from 13 to 66 years. The incidence of fractures in men was 37.2%; in women it was 16.8%. On the basis of their study, the authors also concluded that the fifth, fourth, and sixth thoracic vertebrae were most commonly involved, in that order; the

incidence of fractures doubled with preexisting osteoporosis; the preexistence of kyphosis, scoliosis, arthritis, nuclear change, or old fracture did not predispose the patient to further fracture; and the age of the patient was not a significant factor.

Most of the studies⁵ on the incidence of these fractures in electroconvulsive therapy (ECT) were not adequately controlled, with the result that it is difficult to evaluate the variations of incidence reported. Lingley and Robbins,⁶ in a well-regulated study of 230 patients by roentgenograms before and after ECT, reported an over-all incidence of 23% vertebral fractures. The inci-

dence in men was 37%; in women, 13.2%. In patients with osteoporosis, the incidence was 43%. The most commonly fractured vertebrae were the fourth and fifth thoracic; younger and older persons were chiefly affected.

When Meschan and co-workers⁷ studied 212 male patients receiving ECT, they took preshock roentgenograms, films following each of the first five treatments, and films following the 10th, 15th, 20th, and final treatments. The incidence of vertebral fracture in this group was 35.4%, with the third, fourth, and fifth thoracic vertebrae being most prominently affected. The average number of vertebrae fractured was 2.5 per patient. It was their opinion that the age group 30 to 39 was more liable to fracture than any other age group from 20 to 60 years. There was a high correlation between anterior narrowing of any vertebral bodies on the control film and subsequent fracture. Other factors studied, such as race or presence of spondylosis, kyphosis, or Schmorl's nodes, had no relation to the incidence of fracture. Meschan, Scruggs, and Calhoun did not feel qualified on the basis of their study to make any statement about osteoporosis as a factor in these fractures. In almost two-thirds of the patients, the fractures occurred during the first three treatments and, in four-fifths, within the first five treatments. In 41 cases in which treatment was begun with curare, the incidence of fracture was 19.5%; from 57 cases in which curare was administered after fracture, the authors concluded that the use of the relaxant did not help in preventing further progression of the fracture or the occurrence of a new fracture. Only 13 of 212 patients complained of back pain, and 8 of these had fractures.

DESIGN OF STUDY

Our objective was to provide data regarding the following questions: (1) the incidence of fracture of the spine with and without muscle relaxants; (2) the effects of age, sex, bony structure of the spine, and Glissando and Direct methods of treatment on the fracture incidence; (3) location and severity of fractures; and (4) the incidence of asymptomatic fractures and fractures with minimal transient symptoms. The case material for this study was selected from 1,180 men and women admitted to the two floors for psychiatric patients of the Strong Memorial Hospital and Rochester Municipal Hospital during a 13 month period beginning Jan. 1,

1952. Of these, 263 patients received electroconvulsive therapy. A total of 285 courses of treatment (24.1%) were given to these patients, as 22 of them had 2 courses during the period of study. All of the following data are based on 285 courses of ECT. There were 68 men and 195 women, ranging in age from 14 to 76 years. From 1 to 21 treatments per course of ECT were given, the average number of treatments per patient being 7.5.

Technique.—Before and after each course of treatment a roentgenogram of the lateral dorsolumbar spine was taken. During the course of treatment any complaint of back pain, however minimal, was investigated by additional roentgenograms. In all instances, films were taken by the same technique so that comparison was possible. All patients were treated as they lay supine on a semi-padded examination table. The convulsive movements were allowed to follow their own pattern with the exception that light manual restraint was applied to the extremities. A lumbar pad or pad to hyperextend the spine was not used. A rolled gauze mouth gag was used. The electric shock was given by a Med Craft model B-24 machine, which is equipped to deliver the current by the Direct or Glissando methods. With each group the Glissando method was used for six months and the Direct method for the remainder of the study, so that 147 patients were treated by the former and 138 by the latter methods. For various reasons 27 of these Direct method courses and 27 Glissando method courses of treatment were begun and maintained with the muscle relaxant decamethonium bromide (Syncurine). Separate results will be given for the groups treated with and without decamethonium bromide. The dosage of this drug was gaged individually and was considered adequate when there was no resistance to passive stretching during the tonic phase of the convulsion.

Patients Treated Without Decamethonium Bromide.—In the 231 courses of treatment without decamethonium bromide, there were 48 compression fractures of the spine, an over-all incidence of 20.8%. The incidence of fractures in the male population was significantly higher than in the women. Twenty-four out of 56 men, or 42.9%, sustained thoracic fractures, whereas 24 out of 175 women, or 13.7%, sustained such fractures. Although the greatest percentage of fractures occurred in patients under 40 years of age, the number of cases in each age group was so small that this result was not statistically significant (see table).

Direct Versus Glissando: The over-all fracture incidence when the Direct method was used was 25 fractures in 111 courses given, or 22.6%. In 120 courses of treatment given by the Glissando method, there were 23 fractures, or 19.2%. The breakdown of this factor into sexes indicates that, in 13 out of 23 (56.5%) courses of treatment given to men by the Direct method, fractures occurred. In 33 courses of treatment given to men by the Glissando method, 11 fractures (33.3%) occurred. Although not statistically significant, these data would suggest that immediate delivery of a maximal current in men may be conducive to a higher incidence of fracture. In the 88 and 87 women treated by the Direct and Glissando methods respectively, there were 12 fractures in each group, an incidence of 13.6% and 13.8%.

Effect of Bony Structure: Of 163 courses of treatment given to patients with normal preshock roentgenograms of the spine, there were 34 (20.9%) fractures, whereas in 23 courses given to patients whose initial films indicated any degree of osteoporosis there were 10 (43.5%) fractures. This difference is statistically significant. Of 43 courses of treatment given to patients whose roentgenograms showed degenerative and other changes (such as old fractures, epiphysitis, narrowing of vertebral bodies, kyphoscoliosis, and anterior wedging of bodies), 5 fractures (11.6%) occurred. This difference is not statistically significant when compared with the fracture incidence in patients with normal preshock films.

Location and Severity of Fractures: The number of vertebrae fractured per patient ranged from one to six, with an average of 2.2 per patient. All vertebral fractures occurred in the dorsal area of the spine, with the fifth, fourth, and sixth thoracic vertebrae respectively being most commonly involved to a statistically significant degree. Fractures were considered serious if the degree of compression exceeded by more than one-third the original height of the vertebral body. Of the 49 patients with fractures, there were two such cases. All other fractures consisted of minimal compression of the superior cortical plates of the vertebral bodies.

Treatment During Which Fracture Occurred: In 34 cases the treatment was determined during which the fracture occurred. Twenty-four fractures (70.6%) occurred in the first three treatments while 10 occurred in later treatments. That the majority of fractures occur in the first three treatments is statistically significant.

Symptoms: In the 231 courses of ECT given, 45 patients complained of back pain, and therefore roentgenograms were taken during these courses of ECT. Of these, 34 (75.6%) had fractures. The presence of pain as an indication of fracture is not only statistically significant but is also a strong indication for roentgenographic study. With the exception of two patients with moderately severe persistent pain, all patients had mild and transitory symptoms that consisted of interscapular pain, and, in a few patients, radicular pain corresponding to the level of fracture. However, that fracture may occur without pain is indicated by the fact that 15 (30.6%) of the 49 patients who had fractures were without symptoms, and the fracture was discovered only by routine postshock films.

Other Serious Complications: There were other complications as follows: fracture of neck of humerus, one; avulsion of lesser tuberosity of the humerus, one; dislocation of shoulder, two; dislocation of mandible, two; tear of anterior tibial ligament, one; tear of shoulder capsule, one.

Patients Treated with Decamethonium Bromide.—Fifty-four courses of ECT were begun and maintained with decamethonium bromide. In these, 27 patients were treated by the Glissando method and the rest by the Direct method; there were 8 men and 19 women in each group. Of these 54 patients, 45 were over 50 years old. Analysis of the preshock films in these patients is as follows: negative, 6; osteoporosis, 13; degenerative changes, 14; old fracture, 18; kyphoscoliosis, 3. Of this entire group only one patient (1.9%) sustained a vertebral fracture. This incidence compared with the incidence of

fractures in patients who received ECT without a muscle relaxant is highly significant. In 32 of the 34 patients whose fracture was diagnosed during the course of ECT, treatment was continued with decamethonium bromide. Seven of these patients (21.9%) showed either progression of the already existing fracture or new fracture of adjacent vertebrae. Among these patients there were no other serious complications.

COMMENT

The results of our study substantiate the previously known facts that fractures are more likely to occur in men than in women, that age has no statistical value in predicting the occurrence of a fracture, that the fifth,

All figures listed as statistically significant showed a chi square validation of at least $P < 0.02$.

fourth, and sixth dorsal vertebrae respectively are most commonly affected, that most fractures occur during the first three treatments, and that the use of muscle relaxants significantly reduces the incidence of fracture.

Although there has been general agreement concerning these facts, there has been much disagreement on the prevalence of these fractures. We feel it is significant and of interest that in those series similar to ours in which large numbers of patients were studied by roentgenograms taken before and after ECT,⁸ there is a high concordance with our results, both as to over-all incidence and as to its variation according to sex difference. This is in sharp contrast to those series reported in which routine x-ray investigations were not carried out. From the above data and the fact that 15 of our 49 fractures caused

8. Easton and Sommers,^{4c} Lingley and Robbins,⁶ Meschan.⁷

no symptoms and were discovered only on the film that is taken as routine procedure after ECT, we have concluded that any accurate evaluation of the incidence of these fractures must include films taken both before and after ECT. Clinical facts substantiate this viewpoint because frequently the only thing visible by roentgenogram is minimal compression of the superior plates of the vertebrae, so that, unless a control film is available for comparison, these fractures might be overlooked entirely. The majority of fractures occur early in the course of treatment while the patients are likely to be most inaccessible and when it would be most difficult to elicit the transient pain that accompanies these fractures. This point is illustrated by the fact that Weinland,⁵⁶ in a study of 418 patients using presence of pain as the criterion for x-ray examination, found the incidence of fractures among schizophrenic patients to be one-fifth as high as among depressed patients. He attributes this to the fact that the nature of the schizophrenic illness is such that these patients complain less of physical pain. Analysis of the 15 patients of our series in whom symptoms of fracture were not elicited indicates that 8 of them were severely disturbed and inaccessible at the time ECT was begun. One other patient had a moderate language barrier, and another showed moderate hypochondriasis as part of the presenting illness, so that any back pain may have been masked by the other symptoms. Although pain is not a consistent accompaniment of fracture, its importance is indicated by the fact that 75.6% of our patients who complained of back pain had fractures.

From our series it would seem that the only physical factor that definitely predisposes a patient to fracture is the presence of osteoporosis. Our finding that the incidence of fracture with preexisting osteoporosis is more than double the general incidence confirms the almost identical finding of Easton and Sommers,⁴⁸ who used pentylene-tetrazol, and Lingley and Robbins,⁶ who used ECT.

Although we cannot statistically support the following hypothesis, it is our impression that a strong muscle mass with violent muscular contraction predisposes to fracture. This is supported by the consistently higher incidence of fractures in men in all series reported. Since the actual mechanism of fracture is still unknown, there have been many attempts to prevent occurrence of fracture by modifications in the technique of administering ECT. These modifications have involved the positioning of the patient, the method of restraint, and the means of initiating the electric shock. Our decision not to hyperextend the spine and to allow freedom of convulsive movements evolved from the feeling that active restraint would predispose to long bone fractures, which are of much greater clinical significance than vertebral fractures. The fact that the incidence of vertebral fractures very closely approximates that of Meschan⁷ (in men) and Lingley and Robbins⁶ (in men and women), despite the fact that in both these series greater restraint and hyperextension were used, indicates that position of the patient and method of restraint are not significant factors. In regard to the method of initiating the electric shock, our re-

sults comparing the Glissando and Direct methods indicate that this variation produces no appreciable change in the fracture incidence.

From our results it would appear that the only variation in technique that affects the incidence of fractures is the use of a muscle relaxant, as indicated by the fact that the over-all fracture rate fell from 20.8% to 1.9% with decamethonium bromide. The efficacy of this modification in our series contrasts with the 19.5% incidence of fractures found by Meschan⁷ with curare. It should be noted, however, that 21.9% of our patients who received decamethonium bromide after sustaining a fracture showed progression of the existing fracture or occurrence of a new fracture. In Meschan's⁷ series, 46.6% of his patients who received curare after fracture occurred showed progression of fracture or appearance of a new fracture. These data suggest that muscle relaxants are more effective in the prevention of an initial fracture than in arresting the progression of such fracture or in preventing the appearance of a new fracture.

We are in agreement with previous studies that have indicated that the presence of these fractures is of little clinical significance in the vast majority of cases. The initial symptoms, if present, are minimal and transient and impose little orthopedic disability. Polatin and Linn⁹ found no orthopedic or neurological sequelae in their 10 year follow-up of patients sustaining compression fractures during pentylene-tetrazol treatment. In none of our cases, including the two "serious" fractures, was orthopedic treatment thought necessary by the consultant.

Despite the relative unimportance of these fractures, it is of obvious advantage to both the patient and the physician to prevent their occurrence when possible. It has been our practice to use a muscle relaxant prophylactically in those patients whose preshock examination shows findings that would predispose to fracture, such as osteoporosis or large muscle mass. Our figures and the data of others⁷ indicate that muscle relaxants are not completely effective in preventing the progression or further occurrence of fracture, but as yet there is no statistically reliable series to show what the incidence of this progression would be in continuing treatment after fractures without the use of such relaxants. Until such data are available, we shall continue the use of these relaxants routinely in those patients who have sustained fractures and in whom it was indicated to continue treatments.

SUMMARY

Two hundred and eighty-five consecutive courses of electroconvulsive therapy (ECT) given in a general hospital were studied by means of preshock and postshock roentgenograms to discover the incidence of vertebral fracture. In 72 courses of ECT given to men and 213 courses of ECT given to women, the over-all fracture incidence was 20.8%. The rate in men was 42.9%; in women, 13.7%. Fifty-four patients began ECT with decamethonium bromide (Syncurine) with a resultant fracture incidence of 1.9%. Osteoporosis and sex of the patient were significant in the incidence of fractures. Age, position of patient, restraint, and method of initiating the current did not influence the fracture incidence. The indications for use of muscle relaxants are discussed.

CLINICAL NOTES

CARDIAC ARREST AFTER INTRAVENOUS ADMINISTRATION OF PROCAINE AMIDE (PRONESTYL)

REPORT OF A CASE IN WHICH THERE WAS SUBSEQUENT RECOVERY

William Weingarten, M.D.

Nicholas J. Galluzzi, M.D.

and

Alexander A. Doerner, M.D., Staten Island, N. Y.

The quinidine-like properties of procaine on the heart have been known for a long time, but the drug is so rapidly hydrolyzed in the blood stream that the action on the heart is rather unpredictable. Lately procaine amide (Pronestyl) hydrochloride has gained wide use in cardiac arrhythmias. Procaine amide is not hydrolyzed by the body enzymes as quickly as procaine, is therefore longer acting, and has been found to be active when administered orally. Procaine amide can be given intravenously with greater safety than quinidine and on occasion may revert a cardiac arrhythmia to normal sinus rhythm even after quinidine failure.¹ L. C. Mark and co-workers² and Goldberg and Cotten³ have done excellent experimental work on dogs in cardiac arrhythmias and have proved the value of procaine amide in prevention and control of ventricular arrhythmias.

Procaine amide was used successfully on human beings for the treatment of ventricular premature contractions and ventricular arrhythmias. Stearns and co-workers⁴ were able to abolish ventricular tachycardia in 7 out of 8 patients, and Kayden and associates⁵ reverted ventricular tachycardia in 13 of 15 patients to normal sinus rhythm with procaine amide given intravenously. Main-

zer⁶ found procaine amide used intravenously to be the drug of choice in the treatment of paroxysmal ventricular tachycardia during anesthesia, particularly for thoracic surgery.

Side-reactions have been noted during the use of this drug and the more common ones are hypotension and widening of the QRS complexes. Severer reactions were chills and fever after oral use of procaine amide,⁷ and two cases of agranulocytosis⁸ were reported due to the drug. Animal experiments have shown that procaine amide can produce ventricular fibrillation or atrioventricular block and can lead to cardiac arrest. Kayden and associates⁵ noted that one of their patients in whom ventricular fibrillation developed died, and Kinsman and associates⁹ noted that two of their patients died shortly after administration of procaine amide, but their condition was so poor that no definite conclusions could be drawn as to the relationship of the drug to their demise. Miller and co-workers¹⁰ observed ventricular fibrillation followed by a short period of cardiac arrest when procaine amide was administered to a patient with complete heart block. Acierno and associates¹¹ noted increase in intraventricular block and subsequent cardiac standstill in one case of ventricular tachycardia treated with procaine amide administered intravenously, but this patient, too, was moribund when treatment was begun, and no definite conclusion could be reached as to causal relationship. On the other hand, the authors noted development of ventricular tachycardia after intravenous injection of procaine amide in a case of auricular flutter and preexisting bundle branch block.

REPORT OF A CASE

In May, 1951, a 30-year-old Negro merchant seaman was found to have pulmonary tuberculosis, and in spite of therapy with streptomycin and *p*-aminosalicylic acid (PAS) a cavity developed in the right upper lobe in January, 1952, and by August, 1952, he needed surgical therapy.

Examination of the cardiovascular system revealed pulse rate of 84 per minute, blood pressure 100/60 mm. Hg, and normal sinus rhythm with no murmurs. The remainder of the physical examination was normal. Resting electrocardiogram was normal. The teleroentgenogram revealed a normal cardiac silhouette.

On Aug. 4, 1952, the patient was subjected to a right upper lobectomy. Preoperative medication consisted of morphine sulfate, 16 mg., scopolamine, 0.65 mg., and secobarbital (Seccenal), 100 mg. Endotracheal anesthesia was induced with ether and continued with cyclopropane and oxygen. A slow intravenous drip of procaine hydrochloride (0.6%) was given continuously as a prophylactic measure against cardiac arrhythmias. The operation was started at 8:30 a. m.; at 9:00 a. m. 20 mg. of hexamethonium chloride was given intravenously to control the hypertensive level of 210/120 mm. Hg that had developed after intubation. The blood pressure returned to previous levels. An additional 20 mg. was given at 11 a. m. because hypertension recurred. The operation progressed uneventfully, and blood pressure and pulse were stable at 120/70 mm. Hg and 80 per minute respectively until 1:15 p. m. when the pulse was found to be irregular. At 1:25 p. m. an electrocardiogram revealed multiple premature ventricular contractions from the same focus and ventricular tachycardia developed while the tracing was being recorded. At 1:30 p. m., 250 mg. of procaine amide hydrochloride was given slowly intravenously. The continuous electrocardiogram showed a widening of the QRS complexes within one minute (see Fig. 1). By 1:40 p. m., the QRS complexes returned to the normal duration, and, since the ventricular tachycardia persisted, the patient's condition seemed precarious, and at 1:50 p. m. a dose of procaine amide was given. At 1:55 p. m., the

no symptoms and were discovered only on the film that is taken as routine procedure after ECT, we have concluded that any accurate evaluation of the incidence of these fractures must include films taken both before and after ECT. Clinical facts substantiate this viewpoint because frequently the only thing visible by roentgenogram is minimal compression of the superior plates of the vertebrae, so that, unless a control film is available for comparison, these fractures might be overlooked entirely. The majority of fractures occur early in the course of treatment while the patients are likely to be most inaccessible and when it would be most difficult to elicit the transient pain that accompanies these fractures. This point is illustrated by the fact that Weinland,⁵⁶ in a study of 418 patients using presence of pain as the criterion for x-ray examination, found the incidence of fractures among schizophrenic patients to be one-fifth as high as among depressed patients. He attributes this to the fact that the nature of the schizophrenic illness is such that these patients complain less of physical pain. Analysis of the 15 patients of our series in whom symptoms of fracture were not elicited indicates that 8 of them were severely disturbed and inaccessible at the time ECT was begun. One other patient had a moderate language barrier, and another showed moderate hypochondriasis as part of the presenting illness, so that any back pain may have been masked by the other symptoms. Although pain is not a consistent accompaniment of fracture, its importance is indicated by the fact that 75.6% of our patients who complained of back pain had fractures.

From our series it would seem that the only physical factor that definitely predisposes a patient to fracture is the presence of osteoporosis. Our finding that the incidence of fracture with preexisting osteoporosis is more than double the general incidence confirms the almost identical finding of Easton and Sommers,⁴⁸ who used pentylentetrazol, and Lingley and Robbins,⁶ who used ECT.

Although we cannot statistically support the following hypothesis, it is our impression that a strong muscle mass with violent muscular contraction predisposes to fracture. This is supported by the consistently higher incidence of fractures in men in all series reported. Since the actual mechanism of fracture is still unknown, there have been many attempts to prevent occurrence of fracture by modifications in the technique of administering ECT. These modifications have involved the positioning of the patient, the method of restraint, and the means of initiating the electric shock. Our decision not to hyperextend the spine and to allow freedom of convulsive movements evolved from the feeling that active restraint would predispose to long bone fractures, which are of much greater clinical significance than vertebral fractures. The fact that the incidence of vertebral fractures very closely approximates that of Meschan⁷ (in men) and Lingley and Robbins⁶ (in men and women), despite the fact that in both these series greater restraint and hyperextension were used, indicates that position of the patient and method of restraint are not significant factors. In regard to the timing of initiating the electric shock, our re-

sults comparing the Glissando and Direct methods indicate that this variation produces no appreciable change in the fracture incidence.

From our results it would appear that the only variation in technique that affects the incidence of fractures is the use of a muscle relaxant, as indicated by the fact that the over-all fracture rate fell from 20.8% to 1.9% with decamethonium bromide. The efficacy of this modification in our series contrasts with the 19.5% incidence of fractures found by Meschan⁷ with curare. It should be noted, however, that 21.9% of our patients who received decamethonium bromide after sustaining a fracture showed progression of the existing fracture or occurrence of a new fracture. In Meschan's⁷ series, 46.6% of his patients who received curare after fracture occurred showed progression of fracture or appearance of a new fracture. These data suggest that muscle relaxants are more effective in the prevention of an initial fracture than in arresting the progression of such fracture or in preventing the appearance of a new fracture.

We are in agreement with previous studies that have indicated that the presence of these fractures is of little clinical significance in the vast majority of cases. The initial symptoms, if present, are minimal and transient and impose little orthopedic disability. Polatin and Linn⁹ found no orthopedic or neurological sequelae in their 10 year follow-up of patients sustaining compression fractures during pentylentetrazol treatment. In none of our cases, including the two "serious" fractures, was orthopedic treatment thought necessary by the consultant.

Despite the relative unimportance of these fractures, it is of obvious advantage to both the patient and the physician to prevent their occurrence when possible. It has been our practice to use a muscle relaxant prophylactically in those patients whose preshock examination shows findings that would predispose to fracture, such as osteoporosis or large muscle mass. Our figures and the data of others⁷ indicate that muscle relaxants are not completely effective in preventing the progression or further occurrence of fracture, but as yet there is no statistically reliable series to show what the incidence of this progression would be in continuing treatment after fractures without the use of such relaxants. Until such data are available, we shall continue the use of these relaxants routinely in those patients who have sustained fractures and in whom it was indicated to continue treatments.

SUMMARY

Two hundred and eighty-five consecutive courses of electroconvulsive therapy (ECT) given in a general hospital were studied by means of preshock and postshock roentgenograms to discover the incidence of vertebral fracture. In 72 courses of ECT given to men and 213 courses of ECT given to women, the over-all fracture incidence was 20.8%. The rate in men was 42.9%; in women, 13.7%. Fifty-four patients began ECT with decamethonium bromide (Syncurine) with a resultant fracture incidence of 1.9%. Osteoporosis and sex of the patient were significant in the incidence of fractures. Age, position of patient, restraint, and method of initiating the current did not influence the fracture incidence. The indications for use of muscle relaxants are discussed.

due to obstruction. This green speckling is, however, not pathognomonic of extrahepatic obstruction, since it is occasionally observed in hepatitis with marked biliary stasis, especially the cholangiolitic type. It is not only the macroscopic appearance that is deceptive, for it is in these very cases that the histological picture often fails to differentiate between parenchymal and obstructive jaundice. The green speckling is not destroyed by fixation, but is rather accentuated since the fixative bleaches the rest of the lobule.

In viral and toxic hepatitis and in jaundice complicating cirrhosis, the specimen is pale and uniformly icteric, without any green speckling. If some speckling is present, it is usually slight and, apart from cholangiolitic hepatitis, never approaches the speckling of obstructive jaundice, either in size of spot or depth of green. In the acute stage of viral hepatitis, hyperemia is sometimes clearly visible.

In fatty metamorphosis the whole core is rather pale and is moderately translucent on transillumination. The specimen also appears anemic. In cirrhosis the core is also pale but is not translucent unless much fat is present. In two instances of advanced postnecrotic cirrhosis with the diagnosis of grossly nodular livers confirmed at necropsy or at operation, the specimens disintegrated in spite of careful handling; similarly, numerous specimens obtained by the biopsy needle at necropsy also disintegrated despite every precaution. Careful microscopic examination of the needle specimens obtained both from the patients and from the cadavers revealed no evidence of cirrhosis. Histological examination of large slices of liver at postmortem examinations revealed many lines of cleavage between the parenchyma and the coarse fibrous bands, and it appeared that the biopsy specimens must have fragmented at similar weak points. Thus fragmentation of the biopsy specimen despite careful handling should suggest the possibility of hepatic cirrhosis, even without histological confirmation.

Metastatic carcinoma of the liver has a dead-white appearance and is most obvious when the metastasis stands out in marked contrast in a specimen that is mainly normal. When the whole core is neoplastic it is still quite obvious, but the pallor of a cirrhotic specimen may mislead one for want of a standard; if one is in doubt, it is unlikely that the appearance is due to metastasis. On four occasions creamy pus-like fluid has been aspirated; smears revealed necrotic malignant cells.

The follicles of Boeck's sarcoid and of miliary tuberculosis are not apparent on superficial examination. However, if the specimen is transilluminated, the rounded follicles are easily detected, for they are brightly translucent and contrast sharply with the opaque normal tissue (fig. 2B). This translucency has to be looked for in the fresh specimen, as it dims gradually at room temperature and disappears immediately on fixation. Once the follicles have been localized by transillumination, they are easily detectable under direct light as well-defined pale areas. These appearances have been noted in each of the 11 cases of sarcoidosis and 2 of miliary tuberculosis in which biopsies have been done since this observation was first made. The pathologist is frequently unable to differentiate the various granulomas unless he can find caseation or tubercle bacilli. Therefore the gross demonstration of

the translucent foci, the granulomas, may be just as helpful as the microscopic examination for correlation with the clinical findings. Detection of the follicles also indicates at once that the biopsy has been successful; if these foci are not seen, the biopsy may be repeated without waiting for the histological report, especially if the clinical evidence for some granulomatous condition is strong. Finally the position of the follicles may be reported to the pathologist, thus allowing him to cut his sections in the right place.

Pallor and translucency should be carefully evaluated when present at the proximal end of the specimen, where they are often seen as a result of the suction applied during the biopsy; although they may mislead the unwary, they do not approach the white opacity of carcinoma or the clear translucency of the granulomas. The glass tubes should therefore be marked at one end with a substance such as sealing wax and the specimen should always be inserted through that end.

In hemochromatosis, the biopsy specimen is at once seen to be unusually brown in color; after the specimen has been standing in methylal-saline solution this hue intensifies, in contrast to other specimens, which are blanched by this fixative. Furthermore, the pale strands of fibrous tissue stand out against the brown color, permitting one to make an accurate forecast of cirrhosis in addition to hemochromatosis.

OBSERVATIONS

Observations During Liver Biopsy.—The duration of bleeding from the skin incision is an excellent indication of adequate hemostasis; thus the biopsy should not be performed until the incision has stopped bleeding. If the bleeding lasts longer than 10 minutes, the biopsy should be postponed for further investigation. This precaution has saved me from performing biopsies on patients with abnormal bleeding tendencies due to uremia, thrombocytopenia, and low prothrombin levels, which were incorrectly reported as normal or which fell suddenly from normal.

The resistance to the needle is increased in well-developed cirrhosis, but not in metastatic carcinoma. Patients with hepatic metastases usually experience no sensation of any kind during the biopsy; since other patients are usually aware of a vague sensation of pushing or pulling, it seems probable that the nerve supply of Glisson's capsule is often interrupted in metastatic carcinoma of the liver.

Either during infiltration with a local anesthetic or during the actual biopsy, the presence of ascites may be determined by withdrawing ascitic fluid into the syringe or, on occasion, by collecting some fluid escaping through the biopsy track. Similarly one may obtain clear fluid in cystic disease of the liver, pus from an amebic abscess, blood from a hemangioma, bile from a distended bile duct in obstructive jaundice, and hooklets from a hydatid cyst.

Application to Other Techniques.—The specimen obtained with the Vim-Silverman needle lies rather obstinately within the split inner needle, from which it is usually dislodged with some form of hook and delivered straight into the fixative. To permit naked-eye examination, the biopsy specimen should be removed with a piece of nonglossy paper, to which it readily adheres, or with a

change had occurred in the electrocardiogram or in the patient's condition and 200 mg. of procaine amide was given. Within one minute, QRS widening again appeared. By 1:50 p. m., the QRS complexes returned to their original duration and an additional 200 mg. of procaine amide was given, with subsequent widening of the QRS complexes. At 1:55 p. m., although slight QRS widening persisted, in view of the patient's lack of response, an additional 250 mg. of procaine amide was given. During the next few minutes progressive QRS widening occurred, and at 2:00 p. m. cardiac standstill supervened. The exposed heart was immediately massaged manually and epinephrine was injected into the left ventricle. At 2:15 p. m., spontaneous ventricular contractions were observed and the continuous electrocardiogram record demonstrated a reversion to normal in reverse order to the pattern of the evolution of the cardiac standstill. The patient had an uneventful recovery, and several days later a follow-up electrocardiogram revealed an entirely normal pattern.

COMMENT

Although mild and severe reactions during the intravenous administration of procaine amide have been described, to the best of our knowledge no authentic case

Electrocardiogram taken continuously during a right upper lobectomy on a 30-year-old Negro seaman, who had pulmonary tuberculosis.

of cardiac standstill after intravenous administration of this drug has been reported. It is known that during inhalation anesthesia, particularly in intrathoracic explorations, ventricular premature contractions, ventricular tachycardia, and cardiac arrest, may suddenly occur and require emergency treatment. Our patient had received a variety of drugs preoperatively, and during anesthesia, which too may have precipitated the bout of ventricular tachycardia and contributed to the cardiac arrest. In our case there was marked widening of the QRS complexes (which is known to be a side-reaction of procaine amide administration) after each dose of procaine amide, and the progressive widening of the QRS after the last dose led to complete cardiac arrest. In view of the continuous electrocardiogram tracings that were taken during the administration of the drug and revealed immediate changes after each dose, the relationship between the intravenous administration of procaine amide and cardiac arrest seems well established.

ADDENDUM

Since the preparation of this manuscript, a report by Marvin A. Epstein, in the *American Heart Journal* of June, 1953, describes the occurrence of three cases of ventricular standstill during the intravenous procaine amide treatment of ventricular tachycardia.

SURGICAL REPAIR OF INTRAVENTRICULAR SEPTAL DEFECTS

REPORT OF A CASE

Earle B. Kay, M.D.

and

Henry A. Zimmerman, M.D., Cleveland

Evidence reveals that a high proportion of patients with intraventricular septal defects must lead lives of restricted activity and that others die prematurely. Intraventricular septal defects are commonly located high in the septum and connect the left ventricular chamber immediately proximal to the aortic valve to the right ventricular chamber in the region of the median leaflet of the tricuspid valve. Defects in this region may be associated with other defects, such as pulmonic or infundibular stenosis and overriding of the aorta. Less commonly intraventricular defects may be located lower in the muscular septum. They result from failure of the lower ventricular septum growing from the apex to meet and fuse with the downward growing aortic septum.

This report deals with the surgical closure of intraventricular septal defects uncomplicated by other abnormalities. The greater pressure within the left ventricle causes a left to right shunt of blood during ventricular systole, increased blood flow to the lungs, pulmonary hypertension, sclerosis of the pulmonary vessels, and cardiac hypertrophy on the right side.

Delay in the surgical treatment of intraventricular septal defects has resulted from the failure of development of an effective but simple heart-lung preparation to allow safe, open operations within the chambers of the ventricles and the danger of air emboli occurring during cardiomyotomy when refrigeration is employed. Closed methods have been employed in which the intraventricular septal defect was plugged with pericardial grafts, but such grafts have been shown to become atrophic after several months.

TECHNIQUE

The technique to be described has the advantages of being simple and safe and adaptable to the closure of the majority of septal defects. An anterolateral exposure through the left third or fourth interspace is employed. The sternochondral junction of either or both the third or fourth costal cartilage is detached from the sternum. Further exposure can be obtained by transecting the sternum or rongeur the lateral border. A purse-string suture is placed in the anterior wall of the right ventricle in the center of which an opening is made for insertion of the index finger of the left hand to explore the right ventricle, septum, and pulmonary and tricuspid valves for other defects. The size and location of the defect is determined. The jet of blood pouring into the right ventricle

can easily be palpated in the region of the median cusp of the tricuspid valve. By employing a large upholstery needle and no. 1 nonabsorbable surgical suture, the needle is inserted into the ventricular chamber in the region of the pulmonary conus as illustrated in the figure. The tip of the needle is then directed by the index finger within the ventricular chamber to engage the anterior and posterior lips of the septal defect and then through the ventricular wall at a lower level. The needle is removed, and an instrument is passed into the ventricular chamber along the index finger to catch the two ends of the suture and to bring them out of the myotomy opening. The ends are then tied and the knot pushed into the chamber; this approximates the two lips of the defect. Scissors are then inserted along the index finger, and the ends of the suture are cut. It appears that three to four sutures are required to adequately close defects that approach the size of the end of the finger. The myotomy incision is then closed by interrupted suture, and the purse-string suture is removed. The pericardium is closed loosely to allow drainage into

Diagrammatic sketch of the heart showing index finger of the left hand inserted into the right ventricle. The position and character of the septal defect is determined. A large suture ligature is passed through the ventricular wall, through the edges of the septal defect, and out through the ventricular wall.

the pleural space. This is followed by closure of the chest incision in the usual manner with drainage. Refrigeration of the patient adds to the safety of the operation.

REPORT OF A CASE

A 21-year-old white woman was admitted to St. Vincent Charity Hospital on May 20, 1953. For several weeks following birth, she had had a bluish color but otherwise had not been cyanotic. She had had known congenital heart disease since birth. Activity was always restricted because of dyspnea on ordinary exertion. She suffered from frequent respiratory infections and had pneumonia at the age of 13. There had never been any episodes of cardiac failure.

The physical examination revealed a slightly obese woman who was somewhat dyspneic but who otherwise did not appear acutely or chronically ill. The blood pressure was 105 systolic and 70 diastolic. The results of the examination, except for the heart abnormalities, were essentially normal. There was a loud systolic murmur heard over the entire precordium, but this was loudest in the third and fourth interspaces. A thrill was palpable in the same area.

Roentgenograms of the chest, including those taken after a barium swallow, and cardiac fluoroscopy revealed an enlarged right auricle and a prominent pulmonary conus. The heart

was not appreciably enlarged. An angiocardigram revealed a shunt between the right and left sides of the heart with visualization of the aorta within one second. It could not be determined whether the shunt was between the auricles or the ventricles. The aorta appeared small, and the pulmonary conus and artery appeared large. There was delayed passage of the dye through the pulmonary circulation with suggestive evidence of revascularization of the pulmonary artery. The electrocardiogram revealed a right axis deviation. Cardiac catheterization studies gave the following results. Pressure (mm. Hg) values were, in the right auricle, 5/1; in the right ventricle, 80/3; and, in the femoral artery, 118/74. Oxygen concentration (vol. %) was, in the right auricle, 14.2; in the right ventricle, 15.9; in the femoral artery, 17.92; in the superior vena cava, 13; and in the inferior vena cava, 12.5. The oxygen capacity was 18.7 vol. %. The catheter could not be placed in the pulmonary artery on numerous attempts. This is not unusual in patients who have an elevated pulmonary arterial pressure.

An operation was performed on May 27, 1953, through a left anterolateral exposure. The technique employed was similar to that already described. The woman's temperature was lowered to 84 F throughout the operative procedure. The patient withstood the operation well, but the first 48 postoperative hours were complicated by difficulty in maintaining the blood pressure and by pulmonary edema. Thereafter improvement was progressive. The patient was discharged on the 14th day. Check-up examination three months later revealed considerable improvement in the patient's dyspnea.

CONTRACTION OF LEFT LEAF OF DIAPHRAGM COINCIDENT WITH CARDIAC SYSTOLE

Albert Sjoerdsma, M.D., Ph.D., Bethesda, Md.
and

William B. Gaynor, M.D., Brooklyn

The subject of this report is a patient who showed the phenomenon of contraction of the left leaf of the diaphragm synchronous with systolic movement of the heart. This is the fourth such case to be recorded in the medical literature. The presence of vigorous abdominal pulsations—in each of these four patients initially suggested a diagnosis of aneurysm of the aorta. Tetany due to alkalosis or hypocalcemia was found in each instance, and cessation of the abnormal diaphragmatic movements occurred after corrective therapy.

REPORT OF CASE

A 40-year-old white American seaman entered the hospital on the evening of Oct. 6, 1952, with complaints of epigastric pain, nausea, and vomiting of one week's duration. These symptoms had not been relieved by the ingestion of an unknown amount of "baking soda" and had been persistent for two days. He had been aware of a jerking motion of the left upper quadrant of the abdomen for about 24 hours prior to admission. He gave a history of having had yearly episodes of epigastric pain and vomiting for the previous 10 years, each attack lasting one to two days and being relieved by means of a bland diet and "baking soda." The patient had not considered his previous attacks sufficiently incapacitating to warrant medical attention.

Physical Examination.—The pulse rate was 88, respirations 16 (shallow), blood pressure 110/70 mm. Hg, and temperature 97 F orally. The patient was poorly nourished and lethargic.

From the Clinic of General Medicine and Experimental Therapeutics, National Heart Institute, U. S. Public Health Service Clinical Center, Bethesda, Md. (Dr. Sjoerdsma).

Dr. Frederic C. Bartter assisted in the operation on this case.

and he showed signs of dehydration. The most striking observation was a heaving motion of the left upper quadrant of the abdomen and the adjacent costal margin, with gurgling noises audible to the examiner. The thrusting motion was coincident with the pulse beat, and the gurgling sound apparently resulted from the movement of air and fluid in the stomach. Auscultation of both lung fields showed a high-pitched hissing sound with each thrust that was distinct from the normal breath sounds. Over the precordium this sound was invariably heard between the first and second heart sounds, resembling

Fig. 1.—Electrocardiograms in patient reported on. On Oct. 6, 1952, the heart rate was 102 and the Q-T interval 0.44 seconds. The prolonged Q-T interval is consistent with the metabolic disturbance. Note the alteration (arrows) of repolarization forces, best seen on lead V-4 and a lead taken from the left upper quadrant of the abdomen in the midclavicular line. This deformity of repolarization forces is interpreted as representing electrical potentials associated with the abnormal diaphragmatic contractions. On Oct. 7, 1952, the heart rate was 56. The prolonged Q-T interval (0.56) persisted. The notching of the T wave on lead V-4 may reflect subthreshold diaphragmatic stimuli, since no abdominal pulsations were noted at the bedside at this time. On Oct. 10, 1952, the heart rate was 88 and the Q-T interval was 0.32. This was a normal tracing. Subsequent records showed no change.

a systolic murmur. Moderate epigastric tenderness was noted, and palpation of the pulsating left upper abdominal region changed the character of the gurgling noises. The Trousseau phenomenon was elicited. The Chvostek sign was not elicited.

Course.—On admission the patient was seen by several examiners, and the cause of the heaving motion was obscure. Aneurysm of the aorta was considered to be a possibility. On the evening of admission, fluoroscopy showed vigorous contractions of the left leaf of the diaphragm coincident with cardiac systole, the contractions being superimposed on normal diaphragmatic movement and having a greater excursion during the expiratory phase of respiration. It was not possible to prevent these contractions by changes in the position of the patient or by full inspiration or expiration. The stomach was distended with air and fluid (during the procedure the patient vomited 250 cc. of a milky-appearing liquid). Electrocardiograms were also done at this time (fig. 1). A spiographic tracing (fig. 2) was obtained by having the patient breathe into a closed-circuit respirometer. The reaction was alkaline to a test of the urine by the use of sodium dinitrophenyl-azo-naphthol disulfonate (Nitrazine). By this time it was apparent that the heaving motions were of diaphragmatic origin. The most likely diagnosis appeared to be chronic duodenal ulcer with metabolic alkalosis and latent tetany.

During the first night of hospitalization 2,000 cc. of 5% dextrose in isotonic sodium chloride solution was given intravenously. Sometime during the night the unusual movement of

the left upper quadrant of the abdomen ceased, but the patient continued to be very lethargic and was intermittently disoriented.

The following morning (Oct. 7) roentgenograms of the chest and abdomen were normal; the white blood cell count was 13,000 per cubic millimeter, with a differential count of 72% neutrophils, 18% lymphocytes, and 10% monocytes. The hemoglobin was 13.5 gm. per 100 cc. (Evelyn method) and the hematocrit 45%. The urine gave an alkaline reaction. The specific gravity was 1.019, sugar and acetone negative, and albumin 150 mg. per 100 cc. There were 10 to 15 white blood cells, with many granular and cellular casts per high power field. Serologic studies were negative. Chemical analysis of blood serum revealed sodium, 136.5 mEq. per liter; potassium, 3.12 mEq. per liter; carbon dioxide combining power, 38.2 mEq. per liter; chloride, 70.4 mEq. per liter; pH, 7.79; calcium, 8.6 mg. per 100 cc.; phosphorus, 9.6 mg. per 100 cc., total protein, 5.9 gm. per 100 cc.; and albumin-globulin ratio, 1.4. The blood urea nitrogen was 118 mg. per 100 cc. The data upheld the diagnosis of metabolic alkalosis and indicated renal insufficiency.

During the next three days intensive parenteral fluid therapy was given with solutions containing dextrose, sodium chloride, potassium chloride, and ammonium chloride. By Oct. 10, 1952, the patient's urinary output, which had been low, had returned to normal and the clinical state was much improved. Blood cell counts and blood chemical values had returned to normal except for a blood urea nitrogen level of 87 mg. per 100 cc. From Oct. 10 to Oct. 30, treatment consisted of a progressive Sippy diet and administration of an aluminum hydroxide preparation (Amphogel) and antispasmodics. By Oct. 20 the blood

Fig. 2.—Spirogram in patient reported on, taken Oct. 6, 1952. Small upright waves (arrows) represent inspiratory effect of left diaphragmatic contractions. These waves are seen best on maximal expiration. Rate of the diaphragmatic "flutter" measured from the spiographic tracing is about 90 per minute.

urea nitrogen level had fallen to 20 mg. per 100 cc. and urinalysis results were normal. The patient gained 7 lb. (3.2 kg.) in weight, and the night gastric retention, which had been 1,150 cc. on Oct. 10, had decreased to 200 cc. by Oct. 28. Roentgenograms of the upper gastrointestinal tract were interpreted as giving evidence of pyloric obstruction and deformity of the duodenal bulb consistent with chronic duodenal ulcer, although no ulcer crater could be visualized. Gastric analysis after administration of histamine revealed abundant free acid.

A subtotal gastrectomy was performed on Oct. 31, 1952, and the patient made an uneventful postoperative recovery. Examination of the surgical specimen confirmed the diagnosis

of chronic duodenal ulcer. The patient was discharged from the hospital on Nov. 25, fit for light duty. A follow-up visit on Jan. 8, 1953, indicated continued good health with no recurrence of symptoms.

COMMENT

The phenomenon presented in this report has been described in the literature on three previous occasions. The first report was made in 1932 by Karelitz,¹ who described marked pulsation of the left upper quadrant of the abdomen synchronous with the heart beat in a 9-month-old child with rickets and infantile tetany. The possibility of abdominal aneurysm was considered, but fluoroscopy showed that the underlying disturbance was downward movement of the left leaf of the diaphragm. The pulsations disappeared after antirachitic therapy. In 1944, Widström² briefly discussed a 37-year-old woman with a probable "gastric" tetany in whom movement of the left upper quadrant of the abdomen and a "splashing" sound from the stomach occurred synchronously with the pulse beat. Again, clonic contractions of the left leaf of the diaphragm were noted at fluoroscopy. No follow-up was reported. Söderström,³ in 1945, reported the phenomenon in a 24-year-old man with alkalosis and tetany due to vomiting on the basis of pyloric obstruction, secondary to congenital anomalies of the abdominal viscera. Violent pulsations of the abdomen and "splashing" sounds from the stomach simultaneous with the heart beat were at first thought to be due to an enormous dissecting aneurysm. Fluoroscopy later revealed the cause of the disorder to be powerful left diaphragmatic contractions. The abdominal pulsations gradually decreased in strength and finally disappeared, only to recur after fresh periods of vomiting. On several occasions weak contractions of the diaphragm were observed at fluoroscopy when no abdominal pulsations were distinguishable clinically. The patient became symptom free after a resection of the stomach. There is an obvious similarity between these three cases and the one presented in this report. All were diagnostic problems. Whereas all had tetany, this was attributable to hypocalcemia in one and to alkalosis in the others.

Electrocardiograms taken by Söderström³ showed deformation of the ST and T waves on lead V-4 that were thought to be a manifestation of the diaphragmatic contraction set in motion by the heart. Similar but less marked changes were noted when diaphragm contractions were almost indistinguishable clinically but could still be observed on the fluorescent screen. The changes disappeared when the diaphragm contractions ceased. In 1950, Söderström⁴ reported two additional instances of high frequency diaphragmatic activity that was thought to register on the electrocardiogram; this produced a pattern quite distinct from that in his earlier report and in our case. The electrocardiogram (fig. 1) on our patient on Oct. 6, 1952, showed prolongation of electrical systole and depression of repolarization forces (ST-T) consistent with alkalosis and hypokalemia. In addition there was a deformation (note arrows) of repolarization forces that presumably coincided with the diaphragmatic contractions. By Oct. 7, 1952, the heaving motion of the abdomen was no longer evident clinically. However, there was a suggestion of continued electrical activity contributed by the diaphragm appearing as an

upward displacement of the ascending limb of the T wave in lead V-4. The spirographic tracing (fig. 2) is the first such recording to be reported on a patient with this disorder. Small inspiratory excursions (note arrows) representing independent activity of the left leaf of the diaphragm were easily recorded during maximal expiration.

What is the mechanism in these persons leading to contraction of the left leaf of the diaphragm with each heart beat? Karelitz¹ offered no explanation. Widström² postulated either a direct mechanical irritation of the diaphragm by the heart muscle or a visceromotor reflex with efferent mediation via the phrenic nerve. Söderström³ ascribed the phenomenon to stimulation of the left phrenic nerve during systole, provoked either mechanically or electrically ("through the heart's own action currents"). Of interest in this regard is a report by Carlson and Jacobson⁵ in 1911 directing attention to the frequent occurrence of diaphragmatic contractions synchronous with the heart beat in dogs with severe parathyroid tetany. The contractions were attributed to increased excitability of motor nerves in this condition and were thought to confirm an early observation by Schiff of stimulation of the phrenic nerves by the "action current of the heart." It is clear that the abnormal diaphragmatic stimulation in these various situations is dependent on the increased neuromuscular excitability that exists in the presence of alkalosis and hypocalcemia. Less certain is the manner in which the abnormal impulse is generated. Direct mechanical or electrical stimulation of the diaphragm seems unlikely, since shifts in the relative position of heart and diaphragm in our patient did not prevent the diaphragm from responding with every heart beat. Reflex discharges of cardiac or vascular origin with efferent path via the phrenic nerve probably cannot be ruled out; however, the absence of any case report in which the right leaf of the diaphragm contracted with the heart beat makes this mechanism also appear unlikely. The occurrence of the diaphragmatic stimulation at a time when ventricular volume is decreasing argues against a mechanical stimulation of the left phrenic nerve. The most reasonable hypothesis seems to be that the left phrenic nerve is stimulated by the heart's own action currents. In the human only the left phrenic nerve lies closely adjacent to ventricular myocardium.

SUMMARY

Clonic contractions of the left leaf of the diaphragm synchronous with the heart beat are reported in a 40-year-old man with alkalosis and latent tetany. Three similar cases are cited from the literature. It is postulated that, in the presence of the increased neuromuscular excitability of tetany, electrical stimulation of the left phrenic nerve by the heart's action currents may produce contractions of the left leaf of the diaphragm.

MACROSCOPIC DIAGNOSIS IN LIVER BIOPSY

Richard B. Terry, M.D., London

Although the macroscopic features of the specimens obtained by needle biopsy of the liver are often informative and helpful in diagnosis, they have been disregarded largely because the specimens obtained by the usual techniques are unsuitable for naked-eye examination. This report deals (a) with a method of obtaining, by biopsy, specimens of the liver of adequate size and in suitable condition for macroscopic examination and (b) with the gross appearance of such specimens in various disorders.

The Vim-Silverman needle,¹ which is generally preferred in America, is simple to use. However, the specimen is taken by a split inner needle with a bore of less than 1 mm. that projects only 2 cm. beyond the bevel of the outer needle. The specimen is therefore small, with a maximum volume of about 12.5 cu. mm. It is difficult to prepare for naked-eye examination since it is held inside the split needle, and its gross appearance is distorted by the squeeze of the split needle.

The Iversen-Roholm needle,² more popular in Europe, has a bore of 1.6 to 2 mm. and can be inserted into the liver to any desired depth to obtain specimens of 60 to 90 cu. mm. However, the specimen is usually aspirated into the syringe where it often breaks up and is difficult to handle; while a larger specimen is available for histological examination than with the Vim-Silverman technique, it is no more suitable for naked-eye inspection. The same applies to the Franseen³ needle. The disadvantages of the Iversen-Roholm method may be overcome without losing its advantages by combining the syringe, trocar, and needle into one instrument with suitable modifications; this instrument,⁴ hereafter referred to as the combined instrument, gives large intact specimens that are easily handled and readily examined by the naked eye.

METHOD

The Combined Instrument and Its Use.—The instrument (fig. 1) consists basically of a syringe carrying a biopsy needle on the barrel and a trocar on the plunger. A spring catch on the cap of the syringe engages with the notched piston rod and permits negative pressure to be maintained when the plunger is retracted. In taking the biopsy specimen, the left hand grips the piston handle keeping the plunger, and thus the trocar, stationary, while the right hand thrusts the barrel forward, thus introducing the needle into the liver. In this single movement, the specimen is cut out by the needle, the trocar is removed

from the distal end of the needle, negative pressure is produced within the syringe, and the plunger is locked in its retracted position maintaining suction on the biopsy specimen without further attention from the operator. After rotation of the needle to and fro to loosen the base of the core, the needle is withdrawn.

Manipulation of Biopsy Specimen.—The core of liver is placed in a glass tube, 5 cm. long with a 4 mm. bore, where it can be freely handled without damage and its gross appearance studied with both the naked eye and a

Fig. 1.—The combined liver biopsy instrument.

hand lens. The glass tube magnifies the core somewhat and permits transillumination; it also keeps the core straight and intact, facilitating histological preparation.

To introduce the specimen into the glass tube, the needle is unscrewed from the syringe and a blunt trocar of appropriate size inserted into the needle until the specimen just appears at the bevel; the point of the needle is then placed well inside the glass tube, and the specimen is gently deposited in the tube by retracting the needle with the trocar held still. Any blood on the specimen is immediately washed away and aspirated from the glass tube; the syringe and procaine already employed for local anesthesia may be used for this purpose. The specimen must be examined without delay and before it is placed in fixative, which would make it appear homogenous.

GROSS APPEARANCE

Macroscopic Diagnosis.—The specimen of normal liver has a milk chocolate hue, which varies in depth with the concentration of glycogen and which on closer inspection is seen to be slightly mottled, the darker areas

Fig. 2.—A, speckled biopsy specimen showing obstructive jaundice; B, transilluminated biopsy specimen showing translucent follicles of Boeck's sarcoid.

corresponding to the central zones. The specimen is opaque to transillumination, and no vascularity is visible within the tissue.

In obstructive jaundice, the specimen has a speckled appearance (fig. 2A); against a background paler than normal, the central zones appear as dark green irregular spots up to 1 mm. in diameter. This picture has been noted in each of 27 specimens from patients with obstructive jaundice. If in a patient with jaundice this characteristic picture is absent, the jaundice is probably not

due to obstruction. This green speckling is, however, not pathognomonic of extrahepatic obstruction, since it is occasionally observed in hepatitis with marked biliary stasis, especially the cholangiolitic type. It is not only the macroscopic appearance that is deceptive, for it is in these very cases that the histological picture often fails to differentiate between parenchymal and obstructive jaundice. The green speckling is not destroyed by fixation, but is rather accentuated since the fixative bleaches the rest of the lobule.

In viral and toxic hepatitis and in jaundice complicating cirrhosis, the specimen is pale and uniformly icteric, without any green speckling. If some speckling is present, it is usually slight and, apart from cholangiolitic hepatitis, never approaches the speckling of obstructive jaundice, either in size of spot or depth of green. In the acute stage of viral hepatitis, hyperemia is sometimes clearly visible.

In fatty metamorphosis the whole core is rather pale and is moderately translucent on transillumination. The specimen also appears anemic. In cirrhosis the core is also pale but is not translucent unless much fat is present. In two instances of advanced postnecrotic cirrhosis with the diagnosis of grossly nodular livers confirmed at necropsy or at operation, the specimens disintegrated in spite of careful handling; similarly, numerous specimens obtained by the biopsy needle at necropsy also disintegrated despite every precaution. Careful microscopic examination of the needle specimens obtained both from the patients and from the cadavers revealed no evidence of cirrhosis. Histological examination of large slices of liver at postmortem examinations revealed many lines of cleavage between the parenchyma and the coarse fibrous bands, and it appeared that the biopsy specimens must have fragmented at similar weak points. Thus fragmentation of the biopsy specimen despite careful handling should suggest the possibility of hepatic cirrhosis, even without histological confirmation.

Metastatic carcinoma of the liver has a dead-white appearance and is most obvious when the metastasis stands out in marked contrast in a specimen that is mainly normal. When the whole core is neoplastic it is still quite obvious, but the pallor of a cirrhotic specimen may mislead one for want of a standard; if one is in doubt, it is unlikely that the appearance is due to metastasis. On four occasions creamy pus-like fluid has been aspirated; smears revealed necrotic malignant cells.

The follicles of Boeck's sarcoid and of miliary tuberculosis are not apparent on superficial examination. However, if the specimen is transilluminated, the rounded follicles are easily detected, for they are brightly translucent and contrast sharply with the opaque normal tissue (fig. 2B). This translucency has to be looked for in the fresh specimen, as it dims gradually at room temperature and disappears immediately on fixation. Once the follicles have been localized by transillumination, they are easily detectable under direct light as well-defined pale areas. These appearances have been noted in each of the 11 cases of sarcoidosis and 2 of miliary tuberculosis in which biopsies have been done since this observation was first made. The pathologist is frequently unable to differentiate the various granulomas unless he can find caseation or tubercle bacilli. Therefore the gross demonstration of

the translucent foci, the granulomas, may be just as helpful as the microscopic examination for correlation with the clinical findings. Detection of the follicles also indicates at once that the biopsy has been successful; if these foci are not seen, the biopsy may be repeated without waiting for the histological report, especially if the clinical evidence for some granulomatous condition is strong. Finally the position of the follicles may be reported to the pathologist, thus allowing him to cut his sections in the right place.

Pallor and translucency should be carefully evaluated when present at the proximal end of the specimen, where they are often seen as a result of the suction applied during the biopsy; although they may mislead the unwary, they do not approach the white opacity of carcinoma or the clear translucency of the granulomas. The glass tubes should therefore be marked at one end with a substance such as sealing wax and the specimen should always be inserted through that end.

In hemochromatosis, the biopsy specimen is at once seen to be unusually brown in color; after the specimen has been standing in methylal-saline solution this hue intensifies, in contrast to other specimens, which are blanched by this fixative. Furthermore, the pale strands of fibrous tissue stand out against the brown color, permitting one to make an accurate forecast of cirrhosis in addition to hemochromatosis.

OBSERVATIONS

Observations During Liver Biopsy.—The duration of bleeding from the skin incision is an excellent indication of adequate hemostasis; thus the biopsy should not be performed until the incision has stopped bleeding. If the bleeding lasts longer than 10 minutes, the biopsy should be postponed for further investigation. This precaution has saved me from performing biopsies on patients with abnormal bleeding tendencies due to uremia, thrombocytopenia, and low prothrombin levels, which were incorrectly reported as normal or which fell suddenly from normal.

The resistance to the needle is increased in well-developed cirrhosis, but not in metastatic carcinoma. Patients with hepatic metastases usually experience no sensation of any kind during the biopsy; since other patients are usually aware of a vague sensation of pushing or pulling, it seems probable that the nerve supply of Glisson's capsule is often interrupted in metastatic carcinoma of the liver.

Either during infiltration with a local anesthetic or during the actual biopsy, the presence of ascites may be determined by withdrawing ascitic fluid into the syringe or, on occasion, by collecting some fluid escaping through the biopsy track. Similarly one may obtain clear fluid in cystic disease of the liver, pus from an amebic abscess, blood from a hemangioma, bile from a distended bile duct in obstructive jaundice, and hooklets from a hydatid cyst.

Application to Other Techniques.—The specimen obtained with the Vim-Silverman needle lies rather obstinately within the split inner needle, from which it is usually dislodged with some form of hook and delivered straight into the fixative. To permit naked-eye examination, the biopsy specimen should be removed with a piece of nonglossy paper, to which it readily adheres, or with a

coverslip, which facilitates transillumination. With the Iversen-Roholm, Franseen, and similar aspiration biopsy techniques, the specimen is usually sucked into the syringe. If the syringe is partly filled with saline solution before suction is applied, the specimen is less likely to be damaged and is more easily handled and inspected.

COMMENT

While it is clearly advantageous to be able to determine at the bedside whether a liver biopsy specimen is abnormal and what the abnormality is, it is doubtful whether this advantage alone would recommend the combined instrument in preference to either the Vim-Silverman or the Iversen-Roholm technique. It is therefore emphasized that the combined instrument has other advantages, including simplicity and rapidity of action.

The mortality rate does not preclude larger biopsy specimens, for the rate is about 0.12% with either the Vim-Silverman or the other techniques.⁵ It is probable that in the Vim-Silverman technique the size of the outer needle is more important than the small size of the biopsy specimen in the production of complications and that the double action of the two needles damages the liver more than the single needle of other methods. Using the combined instrument with needles of 2.1, 1.8, and 1.65 mm. internal diameter, I have performed over 300 biopsies without hemorrhage or death and with but one major complication, which was biliary peritonitis in a patient with intrahepatic biliary obstruction.

SUMMARY

A method of obtaining liver biopsy specimens of adequate size and suitable condition for naked-eye examination is reported. The characteristic macroscopic appearances are described; such conditions as parenchymal jaundice, obstructive jaundice, metastatic carcinoma, and granulomas, including tuberculosis and Boeck's sarcoid, may be readily recognized at the bedside.

DEFORMITY OF THE XIPHOID CARTILAGE ASSOCIATED WITH GASTRO-INTESTINAL SYMPTOMS

C. R. Hanlon, M.D.,[†] Bethlehem, Pa.
and

Mary Margaret Miller, M.D., New York

Scant attention has been paid to lesions and abnormalities of the xiphoid cartilage causing gastrointestinal symptoms. This is probably so because the xiphoid is seldom injured, and congenital or developmental abnormalities are seldom noted or looked for. The xiphoid process, the inferior portion of the sternum, juts down into the anterior abdominal wall in front of the liver and can be palpated in the floor of the depression known as the epigastric fossa, or the "pit of the stomach." The process

is usually flat and pointed but may be almost any shape. It consists of cartilage with a core of bone that enlarges with age. Trauma to the xiphoid is observed infrequently since the cartilage is sheltered in the subcostal angle and is usually more posterior than the body of the sternum; however, it may be contused or broken by a force applied against the anterior wall of the chest.

The epigastric syndrome¹ is the term used to refer to epigastric pain localized in the xiphoid region, arising from a malformed but unbroken xiphoid process. The xiphoid is tender on palpation. The patient complains of heaviness in the pit of the stomach. Nausea and vomiting are noted only when the xiphoid is bent back, and there may be pain on deep breathing. Certain actions, such as eating, applying pressure over the xiphoid, and sitting up, increase the discomfort. Lying in the supine position is stated to lessen the pain. We have encountered a case of tack hammer deformity of the xiphoid associated with gastrointestinal symptoms. This is the second such case reported in the literature as far as we have been able to determine.

Roentgenogram of surgically removed xiphoid cartilage of the patient in case reported on, showing tack hammer deformity.

REPORT OF A CASE

A 46-year-old white man was admitted to St. Luke's Hospital on May 12, 1952, complaining of epigastric tenderness of three weeks' duration. There was a history of slight trauma to the xiphoid process when the patient was struck by a baseball as a child. In 1937, the patient had had gnawing, crampy, epigastric pain, and he was put on an ulcer regimen, which did not relieve the symptoms. The pain continued intermittently, occasionally relieved by medication. There was a constant bitter taste in the mouth and frequent gaseous bloating and substernal burning following ingestion of food. There was occasional nausea accompanying the substernal burning, with relief afforded by belching or vomiting. There was no intolerance to fatty food. There was no relief by epigastric massage. When the patient was reclining, his symptoms were eased by lying on the left side. There was no pain related to respiration. Despite symptoms, the patient's appetite remained good, and there was no weight loss. For three weeks before admission, the patient noted exquisite pain in the epigastrium overlying the xiphoid process when pressure was exerted in this area.

Examination revealed a subcutaneous anterior protrusion of the xiphoid with a fishtail deformity of the inferior aspect of the cartilage. The larger prong of the xiphoid was on the right. Movement of the xiphoid reproduced the exquisite pain of which the patient complained. There was mild tenderness to deep palpations in the right upper quadrant of the abdomen and in the epigastrium.

[†] Dr. Hanlon died on Oct. 18, 1953.

Resident at the Memorial Center for Cancer and Allied Diseases, New York (Dr. Miller).

1. Burman, M., and Sinberg, S. E.: *Injury of the Xiphoid*, New York, Columbia University Press, 1952.

Laboratory studies, including a complete blood cell count, urinalysis, and serologic studies, were all normal. Unfortunately, lateral and oblique roentgenograms were not secured before operation. Excision of the xiphoid was performed. A lateral transverse incision was made over the xiphoid process and extended down to the bone. The muscular and fascial attachments of the process were excised subperiosteally, exposing a tack hammer type of xiphoid (see figure). The deformed cartilage was then excised at its articulating surface with the sternum. Closure was routine, wire being used in the skin. The xiphoid measured 5 by 2 by 0.5 cm., with the right lower prong 1.9 by 1.6 cm. and a left prong of 0.3 by 1 cm.

The patient was discharged from the hospital on the third postoperative day. Wound healing was by primary intention. One year after the operation, the patient reported no recurrence of symptoms and considered himself cured.

EPITHELIOMA AND FIBROSARCOMA OF THE PENIS OCCURRING SIMULTANEOUSLY

James H. McDonald, M.D.

and

Norris J. Heckel, M.D., Chicago

The simultaneous combination of fibrosarcoma and epithelial carcinoma in the same penile lesion has not been reported previously. Because of this the following case history is of interest.

REPORT OF A CASE

A 70-year-old white man was admitted to the Presbyterian Hospital on May 17, 1951, with the complaints of a swelling of the glans penis, which he had noticed two weeks earlier, and hemorrhage on two occasions from beneath the prepuce. For the past 30 years, the patient could not retract the prepuce.

The patient was moderately obese and did not appear ill. Examination of the external genitalia revealed a stony hard mass 2 cm. in diameter on the left dorsal aspect of the glans penis beneath the prepuce. A dark brown serous secretion oozed from beneath the prepuce. There were no palpable inguinal lymph nodes. The testes were slightly atrophic. The prostate was normal per rectum. The remainder of the physical examination was normal. On admission the patient's hemoglobin was 13.5 gm. per 100 cc., the red blood cell count 4,480,000, and the white blood cell count 5,500. Examination of the urine revealed 3 red blood cells and 10 white blood cells per cubic millimeter. Culture of the urine revealed no growth.

On May 22, 1951, with the patient under general anesthesia, a dorsal slit was performed, and a well-circumscribed tumor about 2 cm. in diameter was exposed on the left dorsal aspect of the glans penis. A frozen section biopsy revealed a squamous

cell carcinoma. Partial amputation of the penis was carried out. The postoperative course was uneventful, and the patient was discharged from the hospital 21 days after the operation.

The microscopic examination revealed a well-differentiated squamous cell carcinoma arising from an ulcerating epidermis. There were frequent whorling and pearl formation. Scattered through the underlying stroma were numerous tumor giant cells originating from the stromal cells. Transition between the proliferating fibroblasts and the bizarre giant sarcoma cells was observed. The giant cells contained single and multiple nuclei that were highly irregular in shape and staining qualities (see figure). The diagnosis was (1) mixed malignant neoplasm of the penis, (2) squamous cell carcinoma of the penis, and (3) fibrosarcoma of the penis. The patient was followed for 27 months and was completely well. There was no evidence of local or distant metastases.

Photomicrograph showing bizarre giant sarcoma cells and proliferating fibroblasts (X 950).

COMMENT

Of the 12 cases of fibrosarcoma of the penis reviewed in the literature, two were associated epithelial carcinoma.¹ Wheelock and Clark² reported both neoplasms in a patient but in separate penile lesions. Warren and Sommer^{1b} found a fibrosarcoma in the stroma of an epithelioma of the penis after five and one-half years of unsuccessful treatment of the carcinoma.

The metastatic pattern of the fibrosarcoma is of importance in delineating the desirable operative procedure. Metastases disseminate primarily by the blood stream and are generally believed to occur late in the disease. The lungs are commonly involved in metastases, and the regional lymph nodes are not usually affected.³ In these lesions, without local lymph node metastases, partial penile amputation is the procedure of choice.

DIFFICULTIES IN EARLY DIAGNOSIS OF MYOSITIS OSSIFICANS

Leonard Weinstein, M.D.

Samuel H. Fraerman, M.D.

and

Philip Lewin, M.D., Chicago

Myositis ossificans is a benign condition in which there is degeneration of muscle and connective tissue, followed by replacement of these structures with a cellular fibrous tissue that eventually becomes ossified.¹ The usual case of myositis ossificans circumscripta has a definite history of injury to the involved part, followed by pain and swelling in that area. Finally, after several weeks, the typical cloud-like formation of calcified tissue is seen in the muscle mass adjacent to the bone.² Ordinarily there is little difficulty in diagnosing this condition. In the atypical case, however, the diagnosis may become difficult. This case was such a problem. Because of this patient's unusual history and symptoms and because of the problems involved in the differential diagnosis, we feel justified in reporting this case.

REPORT OF A CASE

An 8-year-old boy was brought to our office March 10, 1951, for routine orthopedic examination. He was under treatment for flatfoot and came to be fitted for a corrective shoe. His mother stated that for the past few days he had had some pain in his left thigh and that he limped. Examination showed nothing in the left hip, knee, or foot to account for the symptoms. The patient was advised to rest. On reexamination four days later, there was pain, swelling, and tenderness over the anterior aspect of the left thigh. A roentgenogram showed soft tissue swelling and a faint periosteal elevation of the middle third of the femoral shaft. The child was hospitalized at once for diagnosis and treatment. At this time the patient and his family were asked whether any kind of trauma had occurred. They could not remember any specific injury. Although no history of trauma could be obtained from the patient or his family, the mother stated that on March 3 or 4 the family had been in the country. During this holiday the patient had climbed hills and had gone tobogganing, but he denied injuring himself. Shortly after their return home, he began to complain of pain in his left thigh. The pain was described as an ache aggravated by movement, causing him to limp. The history was noncontributory. The child had had measles, rubella, mumps, and chickenpox. He had had no recent upper respiratory infection but had an allergy to dust for which he was taking 25 mg. of tripeleminamine (Pyribenzamine) hydrochloride twice daily.

Physical examination on March 14, 1951, the day of admission to the hospital, showed a young boy ambulatory but limping because of pain. The left leg was held in external rotation at the hip and in flexion at the knee. Motions to straighten the leg were possible but painful. There was moderate fusiform swelling of the anterior aspect of the left thigh, with diffuse tenderness throughout this area. There was no evidence of cellulitis, nor was there any lymphadenopathy in the groin. His temperature on admission was 101.4 F. Physical examination otherwise showed nothing significant. The patient was given penicillin by injection and placed on a regimen of bed rest.

The patient's hemogram showed a hemoglobin level of 11.8 gm. per 100 cc., or 76% (photoelectric colorimeter, with 15.6 gm. per 100 cc. as 100%); a red blood cell count of 3,810,000 per cubic millimeter; a white blood cell count of 8,350 with a differential count of 47% segmented neutrophils, 39% leukocytes, 3% band cells, 4% lymphocytes, and 6% monocytes. The serum calcium level was 11.1 mg. per 100 cc., and the serum phosphorus level was 5.9 mg. per 100 cc. The serum alkaline phosphatase was 9.2 units, the normal value being between 3 and 15 units. The total serum proteins were 7.1 gm., with the albumin 4.6 gm.

Fig. 1.—Temperature chart of patient in case reported on from time of admission until discharge from hospital.

and globulin 2.5 gm. Agglutination tests for typhoid, paratyphoid, and dysentery organisms were negative. The Kahn test was negative, and the urine was normal. The chest film was normal, and the patch test was negative for tuberculosis. Follow-up white blood cell counts with their differential cell counts were also within normal limits. The temperature graph was that of a septic process (fig. 1).

On March 20, 1951, six days after the patient's admission and about two weeks after the apparent onset of the symptoms, the swelling of the thigh had increased considerably. Induration was present, and the veins of the skin were enlarged and prominent. These observations plus the roentgenogram showing periosteal reaction in the face of a normal white blood cell count caused us to consider bone sarcoma as a possible diagnosis. Since there was some question as to the exact diagnosis, however, other opinions were obtained. These impressions were divided between bone tumor and infection (fig. 2A).

Fig. 2.—Roentgenograms of patient in case reported on. A, on a film taken March 21, 1951, definite periosteal reaction is visible. B, on a film taken April 6 the typical cloud-like formation of ossifying tissue around the femoral shaft is seen.

An aspiration biopsy was done. Fluid withdrawn from the knee was clear and sterile on culture. From the area of maximum tenderness, flecks of clotted blood and amorphous material were obtained. From this material a nonhemolytic Staphylococcus culture was obtained. The Staphylococcus later proved to be a contaminant. After the biopsy the temperature rose several degrees, with peaks of 104 F. The leukocyte count was still within normal limits. Penicillin therapy was stopped.

On March 28, 1951, because of the continuing process and because no definite diagnosis had been made, a surgical biopsy

2. Bowers, R. F.: Myositis Ossificans Traumatica, J. Bone & Joint Surg. 19: 215, 1937. Mercer, W.: Orthopaedic Surgery, ed. 4, Baltimore, Williams & Wilkins Company, 1950. Painter, C. F.: A Consideration of the Etiological Factors in Myositis Ossificans Traumatica, Boston M. & S. J. 18: 45, 1921.

was done by an anterior approach. As soon as the skin was incised, generalized edema of the subcutaneous tissue was seen. When the deep fascia of the thigh was opened, gray-pink necrotic muscle tissue was seen. This was friable and could be dislodged in clumps with the fingers. The periosteum was greatly thickened, and there was increased vascularity between the periosteum and the femur shaft. In fact, the cortical portion of the femur shaft was so porous that it resembled cancellous bone. After seeing the gross tissue and examining a frozen section, the pathologist stated that this lesion was consistent with a sarcoma and advised radical treatment. This would have been either disarticulation of the hip or a very high thigh amputation, since the whole anterior section of the quadriceps and middle third of the femur shaft were involved. We decided to wait for more detailed study of the pathological sections before proceeding with destructive surgery.

After thorough study of the paraffin sections, the pathologist diagnosed this lesion as the pseudosarcoma stage of myositis ossificans. This was corroborated by others specializing in bone pathology. When the next roentgenogram was made, on April 6, 1951, the diagnosis was very apparent roentgenologically (fig. 2B). The typical cloud of well-demarcated ossific material was seen in the muscle mass of the thigh surrounding the femur shaft, the characteristic x-ray appearance of myositis ossificans. Several months later, the roentgenogram showed a definite mass of bone in the quadriceps muscle (fig. 3).

Fig. 3.—Roentgenogram taken in September, 1951, showing definite mass of bone in the quadriceps muscle.

COMMENT

There are several features that prompted reporting this case. The history given by the patient and his family excluded definite knowledge of injury, the one outstanding etiological agent in myositis ossificans circumscripta. Without a history of definite trauma, a rapidly growing bone tumor seemed to be the most possible diagnosis. The age of the patient also was misleading.³ In the literature reviewed by us, no case of myositis ossificans of the quadriceps was recorded in so young a person. Most cases of myositis ossificans of the quadriceps occurred in the second and third decades.

The early roentgenograms did not help in the diagnosis, for they merely showed a single line of periosteal reaction (fig. 2A). This observation can be very misleading. It has been our experience that such a picture indicates only a periosteal irritation, and almost any neoplastic, traumatic, or inflammatory process in the incipient stage can show these periosteal changes.

The course of the fever was another confusing symptom. Fevers of varying degree are expected with bone tumors, especially with Ewing's sarcoma or osteomyelitis; however, it is not generally known that a febrile course can be seen in myositis ossificans. This sign is explained by the fact that necrotic muscle tissue typical of this lesion is being absorbed and causes a foreign protein thermal reaction. Howard,⁴ in his report of five cases of myositis ossificans circumscripta in young men in pre-flight training, noted that each patient ran a fever. We should like to reemphasize that the persistent fever caused us to consider osteomyelitis or Ewing's sarcoma in the differential diagnosis.

Surgical biopsy was the most important diagnostic procedure.⁵ We dismiss needle biopsy as useless and misleading. Frozen sections also may be deceiving and hazardous, because osseous tissue cannot be made into good microscopic sections by this technique. Accurate diagnosis requires material that can be examined morphologically and cytologically in order to differentiate neoplastic from inflammatory tissue.

A number of years ago, this patient's leg might have been amputated at once. It was felt then that biopsy of a neoplastic lesion was hazardous because the procedure stirred up the process and spread the tumor. This concept, fortunately, is no longer held by most workers.

Bone lesions are so often equivocal that, when radical treatment is contemplated, a number of opinions must be obtained. In reviewing cases of the Bone Tumor Registry at the American College of Surgeons, Rossiter⁶ found three instances among about 700 cases in which apparently clinically proved osteogenic sarcoma was proved to be myositis ossificans on pathological examination.⁷ Two of the three patients had amputation. The cases were considered to be five year cures by the submitting physicians. In our judgment, waiting for an accurate diagnosis will not mean the difference between cure and death in true osteogenic sarcoma. The patient should always be given the benefit of all diagnostic procedures before being given radical treatment.

SUMMARY

In a case of myositis ossificans the usual causal factor of definite trauma was lacking. The patient was much younger than is usual in cases of myositis ossificans circumscripta involving the quadriceps muscle. A febrile course is probably a usual observation in the acute phase of myositis ossificans. Surgical biopsy is the most important diagnostic procedure, but it must be interpreted by experts in the field. Amputation to treat a bone tumor should never be done until permanent, good tissue sec-

tions have been examined by competent pathologists. We believe that some of the five year cures reported in osteogenic sarcoma cases may be merely five year survivals of the misdiagnosed pseudosarcoma stage of myositis ossificans.

55 E. Washington St. (2) (Dr. Weinstein).

INVERTED APPENDICAL STUMP SIMULATING CANCER OF THE CECUM

Arkell M. Vaughn, M.D.

and

Jerrold Widran, M.D., Chicago

Roentgenographic diagnosis of abnormality in the cecum can often be misleading. It is not always possible to differentiate neoplastic changes from benign conditions that distort the cecum, even with air contrast studies. The commonest conditions causing difficulty in roentgenographic differential diagnosis in the cecal region are fecal scybala, distortion secondary to an appendical abscess, regional ileitis, tuberculosis, cecal diverticulitis,¹ amebic involvement of the cecum, ulcerative colitis, adhesions following an appendectomy, and an inverted appendical stump. The case we are reporting is that of patient who had had an appendectomy. An irregular filling defect of the cecum, suggestive of a neoplasm on examination, was found at surgery to be an inverted appendical stump.

Gottlieb and associates² emphasized the ever-present danger of misinterpreting feces for an intraluminal defect. Adequate preparation plus air contrast enemas are important. An appendical abscess will give an extraluminal smooth mass but may give enough distortion to make its differentiation from a neoplasm difficult. Regional ileitis, tuberculosis, and adhesions following an appendectomy will, in most cases, involve the ileum as well as distort the cecum. In amebic involvement of the cecum, there is usually evidence of amebic colitis elsewhere.

The presence of an intraluminal defect of the cecum caused by an inverted appendical stump was first described by Artner³ in 1929. With controlled studies, he demonstrated that more than one-third of inverted appendical stumps are persistent and can be visualized in 8% of cases as isolated ring-like structures. Occasionally it is not possible to differentiate a cecal filling defect caused by an inverted appendical stump from a neoplasm and may exist without producing a palpable mass, change in bowel habits, gross blood in the stool, or loss of weight. An unexplained anemia may be the only clinical sign.

From the departments of surgery, Mercy and Cook County hospitals, and Stritch School of Medicine, Loyola University.

The roentgenographic pictures were made by Dr. Fay Squires, Presbyterian Hospital.

REPORT OF A CASE

A white woman aged 39 was admitted to Mercy Hospital in October, 1952. In March, 1952, a supracervical hysterectomy had been performed for uterine fibroids. At that time, an appendectomy was done. Since then she had been in good health until two weeks prior to admission, when, because of dizziness, she sought medical aid. On examination by an internist, a small mass was palpated in the right lower quadrant of the abdomen and an associated mild anemia was found. On advice of the internist, a barium enema was done and revealed a filling defect in the cecum. She was subsequently referred to one of us (A. M. V.) for surgery.

Physical examination on admission revealed an apparently healthy woman. The blood pressure was 130/80 mm. Hg, and the heart and lungs were normal. Abdominal examination revealed a lower right rectus scar, no tenderness, and no mass in the right lower quadrant. There were no gastrointestinal symptoms, abdominal pain, or weight loss. Vaginal examination revealed that the cervix was small, scarred, mobile, and not tender. On bimanual examination, no lower abdominal masses were palpated. Laboratory findings showed red blood cells, 3,660,000; white blood cells, 8,100 per cubic millimeter; and hemoglobin 12 gm. per 100 cc. The feces did not con-

Fig. 1.—Filling defect in the cecum that represents either an appendical stump or a neoplasm.

tain occult blood. The urine was normal. Barium enema was repeated with air contrast studies, and the cecal filling defect seen two weeks previously was unchanged. A neoplasm could not be ruled out so the patient was prepared for a hemicolectomy on the right side. Succinylsulfathiazole (Sulfasuxidine) was administered for seven days, and neomycin was given for the two days preceding surgery.

At surgery, a right paramedian incision removed the old scar. The cecum was dissected free from the surrounding adhesions, brought into the wound, and walled off from the abdominal cavity. External palpation disclosed a small movable mass in the base of the cecum. There were no palpable lymph nodes in the mesentery. The cecum was incised longitudinally through the anterior taenia and the cecal mucosa inspected. The inverted appendical stump was found, but there was no abnormal growth on it or the surrounding mucosa. The stump was excised, and the cecum was closed in two layers.

The pathologist's report stated, "Specimen consists of a mass of tissue measuring 1.5 by 1 by 1 cm. The surface is red and uneven and at one end a small dimple is noted. The other end has been recently sectioned. Section reveals greyish-tan pliable tissue. Microscopic Diagnosis: Inverted stump of appendix. Focal fibrosis and mild focal chronic inflammation."

The postoperative course was uneventful, and the patient was discharged 10 days after surgery. She has been in good health and asymptomatic since. A repeat barium enema, made six months later, showed an absence of the previously irregular ragged defect in the cecum and a smooth filling defect at the site of surgery.

COMMENT

An inverted appendical stump should be considered in the differential diagnosis of a roentgenographic cecal filling defect in every patient who has had an appendectomy. Barium enemas with air contrast studies should be repeated at frequent intervals, and any change in the size of the lesion should be an indication for exploration. A palpable mass in the right lower quadrant, with an associated unexplained anemia, should be an indication for surgery without a prolonged period of observation. Stabins and Dixon⁴ state that any unexplained anemia, with few or no symptoms, should make carcinoma of the cecum suspect. As stated previously, a cecal neo-

Fig. 2.—Smooth rounded filling defect in the cecum is a result of surgery.

plasm may exist without producing a palpable mass, change in bowel habits, gross blood in the stool, or loss of weight. As long as no neoplasm was found on frozen section in our case, it was thought that cutting the protruding tissue flush with the bowel was sufficient, rather than doing a local excision of the cecum.

SUMMARY

Frequent difficulty in making a positive diagnosis of carcinoma of the cecum in the presence of roentgenographic evidence of a cecal filling defect is discussed. Repeated barium enemas with air contrast studies are emphasized as aids in the differential diagnosis of cecal disease. A case in which there was an irregular filling defect of the cecum that was proved at surgery to be an inverted appendical stump is reported.

FATAL HEMORRHAGE FOLLOWING NEEDLE BIOPSY IN UREMIA

REPORT OF A CASE

Samuel Zelman, M.D., Topeka, Kan.

I have encountered only one serious hemorrhage following needle biopsy in over 600 such biopsies of the liver and other organs or tumor masses. In this case, the patient's prognosis was hopeless in any event. However, the experience suggests the advisability of listing uremia among the contraindications to needle biopsy or at least suggests that the increased hazard of hemorrhage in uremia be carefully considered.

REPORT OF A CASE

A 54-year-old white married male rubber factory worker was admitted to Winter Veterans Administration Hospital on Dec. 19, 1952. He stated he had been feeling weak and tired for the past year. Two weeks before admission, he had had an upper respiratory infection together with a periodontal abscess. The diseased tooth was extracted after four days of penicillin therapy. Since then, he had become steadily worse, with anorexia, morning nausea and retching with no vomiting, slight fever, a constant sense of fatigue, headache, shortness of breath on exertion, and intermittent sharp epigastric pain. During the week past, he had been constantly drowsy and unable to work. Diminished excretion of urine, which was dark brown and smoky in appearance, had been present for five days. His fluid intake had been no more than three or four glasses of water per day. For the past four days he had noted morning swelling of the face and hands, and swelling of the feet and ankles during the day. The day before admission, he thought his skin had a yellow tinge. He had lost 10 lb. (4.5 kg.) during the preceding two weeks. There had been no change in the color of his stools, no nocturia, and no nocturnal dyspnea. His personal habits, his history, and his family history were noncontributory. No history of exposure to toxic substances could be obtained, other than his employment handling rubber tires and the occasional use of mercurous chloride (calomel).

The patient was a well-nourished and well-developed white man who appeared moderately ill. He was drowsy but oriented and cooperative. He was 70 in. (1.77 m.) tall and weighed 130 lb. (59 kg.). His usual weight had been 145 lb. (65.8 kg.) prior to the present illness. His temperature was 99.8 F, his pulse rate 60 per minute with occasional extrasystoles, and his blood pressure 136 mm. Hg systolic and 86 mm. Hg diastolic. The skin and scleras were mildly icteric. The pupils reacted normally, extraocular movements were intact, and the ocular fundi were not abnormal. The remaining teeth appeared in fair condition. The chest was symmetrical, with bilaterally equal and adequate expansion. The lung fields were clear to percussion, but fine moist rales were audible at both lung bases posteriorly. The heart was not abnormal. The abdomen was soft. A smooth, tender liver edge was palpable 5 cm. below the right costal margin. Bilateral tenderness in the loin could be elicited by kidney punch. There was slight edema of the face and lower legs. Tendon reflexes were hyperactive. There was no lymphadenopathy.

The leukocyte count on admission was 7,500 per cubic millimeter, with a normal differential count. Erythrocytes numbered 4,100,000 per cubic millimeter. The hemoglobin level was 11.7 gm. per 100 cc. (Haden-Hausser method), the hematocrit was 36%, and the corrected sedimentation rate was 32 mm. per hour (Wintrobe method). Three blood cultures produced no growth. Serum agglutination tests for typhoid H and O antigens, paratyphoid A and B, Brucella abortus, Pasteurella tularensis, Proteus OX19, and heterophil antibody were not significant. Serologic tests for syphilis were negative. Bleeding, clotting, clot retraction, and prothrombin times were within normal limits.

From the Medical Service, Winter Veterans Administration Hospital. This case is reported with the permission of Dr. Joseph E. Smelser of the Medical Service and Dr. Alfred Plaut, pathologist.

The urine was acid, ranged in specific gravity from 1.010 to 1.019, was negative for sugar and bromide, and showed albumin (4+), and macroscopically visible blood with numerous white and red cells visible microscopically, as well as variable numbers of hyaline, granular, and white and red blood cell casts. Tests for heavy metals in the urine were negative. Urine urobilinogen was reported present in high concentration on a single determination. The blood urea nitrogen ranged between 63 and 66 mg. per 100 cc. during the first week of hospitalization. The serum chlorides were 90 mEq. per liter, and the carbon dioxide combining power of the plasma 46 vol. %. The serum bilirubin was 0.2 mg. per 100 cc., the serum alkaline phosphatase was 6.6 Bodansky units per 100 cc., and the inorganic phosphorus content was 6.1 mg. per 100 cc. The cephalin-cholesterol flocculation test was negative, but the sulfobromophthalein sodium (Bromsulphalein) retention at 45 minutes was 17% (5 mg. per kilogram of body weight injected).

Roentgenograms of the chest were taken Dec. 22, 24, and 29. In comparison with a roentgenogram taken in 1948, these showed consistently higher diaphragmatic levels, with widening of the heart shadow presumed to be positional. In addition, infiltrations of somewhat homogeneous appearance were seen in both lower lung fields, varying in location and extent among

cycles (Aureomycin) and penicillin were administered. Fifteen per cent dextrose infusions were repeatedly administered intravenously, with no effect on the oliguria. On Dec. 29, a leukocyte count of 11,850 per cubic millimeter was recorded, with 82% granulocytes. The blood urea nitrogen was now 136 mg. per 100 cc., the creatinine was 12.9 mg. per 100 cc., the serum chloride was 72 mEq. per liter, and the carbon dioxide combining power was 30 vol. %. The serum albumin was 3.3 gm. and the globulin was 2.2 gm. per 100 cc., the calcium was 10 mg. per 100 cc. and phosphorus was 12.4 mg. per 100 cc. The following day, serum sodium was 121.5 mEq. per liter and potassium was 8.2 mEq. per liter. An attempt was made to counter hyponatremia by intravenous infusion of 5% saline solution, of which 200 cc. was administered Dec. 29 and 125 cc. was given Dec. 30.

The patient appeared to be rapidly approaching death, and the impatiently awaited diuresis heralding recovery from what was assumed to be lower nephron nephrosis did not materialize. As a last measure, to help in arriving at a more definitive diagnosis, needle biopsies of the right kidney and of the liver were done at 2:30 p. m. on Dec. 30. Technique on this occasion was flawless; the patient cooperated well despite his stupor, and excellent specimens were obtained bloodlessly with a single puncture of each organ. A light scratching on the surface of the liver was deliberately produced before penetration of the liver was attempted. This maneuver was designed to gauge by the sense of touch the extent of possible laceration if puncture should be carried out during respiration because of the patient's stuporous mental state. The scratches thus defined the respiratory excursion of the liver at this point. The excursion was deemed excessive, and the needle was withdrawn until the patient proved he could cooperate by holding his breath if continuously exhorted to do so throughout the procedure. After that, needle puncture was uneventful. An intercostal approach was used. After the biopsy the patient gradually lapsed into coma, and he died at midnight. Hemorrhage was not suspected from the clinical observations.

The needle biopsies revealed only secondary minor hepatic changes but revealed the presence of severe acute and subacute glomerulonephritis (fig. 1), making evident the hopelessness of the prognosis in the light of the patient's clinical course. At autopsy, the abdominal cavity was found to be filled with 2 liters of fluid and clotted blood. Bilateral pleural effusions were not bloody.

Right perirenal hemorrhagic infiltration was present, possibly amounting to half a liter of blood. The puncture wounds in the convexity of the right lobe of the liver and in the posterior surface of the right kidney were no larger than needle size and showed no surrounding hemorrhagic infiltration of the capsules or parenchyma (fig. 2). On section, the needle tracks were evident as narrow streaks without surrounding hemorrhage. Neither puncture entered any macroscopic vessel or duct, nor did the renal puncture reach the pelvis or calix. It was evident that bleeding in both instances was a result of defection of hemostasis rather than of trauma.

Other observations of interest at autopsy included rheumatic myocardial lesions of varying ages, subendocardial and gastric mucosal hemorrhages, generalized and cerebral edema of moderate degree, persistence of the thymus, and two necrotic foci in the anterior pituitary. The pituitary necroses were 2 to 4 and 7 to 10 days old, according to Sheehan's criteria,¹ and therefore unrelated to the terminal hemorrhage. The liver showed a moderate degree of central stasis and some increase in the portal connective tissue.

The kidneys were large, pale, and smooth, with many sharply circumscribed small surface hemorrhages. They were soft and soggy in texture. The cortices were slightly wider than normal, with fairly distinct striations and with normal outlines of the slightly darker pyramids. The glomeruli were barely visible, and

Fig. 1.—Acute glomerulonephritis, section of needle biopsy of kidney, hematoxylin and eosin stain ($\times 59$).

the films. These presumably represented areas of uremic congestion and edema, although they were interpreted at the time as atypical pneumonias and effusions. An abdominal roentgenogram proved noncontributory. Electrocardiograms taken Dec. 20 and 30 showed slurring and low voltage of the ventricular complexes. The second electrocardiogram showed, in addition, lower and broader P waves, with increase in the P-R interval from 0.16 to 0.24 second, and widening of the QRS from 0.09 to 0.11 second, suggesting the development of myocardial conduction difficulty.

The patient was confused, restless, and drowsy throughout his hospital course. Nausea, vomiting, and diarrhea were intermittent. Abdominal and low back pain and chilliness were noted by the patient. Remittent fever, with temperature as high as 100 F, was present during the first four days of hospitalization, after which the patient was afebrile. Oliguria was present throughout the hospital course, varying from a 24 hour maximum of 370 cc. to a minimum of 60 cc., in general gradually decreasing in quantity until death. Blood pressure remained at normal level. Tetanic muscular twitchings appeared Dec. 28.

Clinical observations pointed to acute hepatitis and a lower nephron nephrosis. The patient was digitalized, and chlortetra-

1. Sheehan, H. L. "Postpartum Necrosis of the Anterior Pituitary," *J. Clin. Endocrinol.* 4:159-214, 1937.

the papillae were not abnormal. The mucosae of the pelvis and calices were irregularly but widely hemorrhagic. Histologically, most of the glomeruli were bloodless; some were filled with leukocytes. Crescents were few. In some glomeruli the vascular loops showed little change, but the capsule was notably thickened next to the vascular pole. There was much interstitial inflammation, consisting mostly of mononuclear cells. Many tubules contained blood and fibrin. Other than the presence of the needle track, there were no gross or microscopic differences between the two kidneys.

COMMENT

For two liters of blood to have spilled into the peritoneal cavity, one must envision a stream of blood amounting to 4 cc. per minute continuously during the nine and one-half hours of the patient's survival. The minor trauma of a puncture wound no more than 3 mm. in diameter cannot by itself account for such hemorrhage. A defect of hemostasis must have been present. The co-existence of hemorrhage from the similarly small needle wound of the kidney, in which less blood was lost presumably because of the lesser distensibility of the perirenal tissues, would appear to confirm the existence of such a defect. The needles entered no large blood vessels. The bleeding time, coagulation time, clot retraction time, and prothrombin time of this patient were determined to be within normal limits. Persistent oozing had not occurred following venipunctures, nor did any occur from the skin incisions of the two needle biopsies. Capillary fragility was not determined. Although hemorrhages were later found in the subendocardial area, stomach mucosa, and renal pelvis, there had been no visible evidence of hemorrhages as petechiae or ecchymoses or of hemorrhagic discharges other than the hematuria connected with the nephritis and a brief and minor epistaxis that occurred Dec. 23.

Uremia has not previously been listed as a contraindication to the performance of needle biopsies.^{1a} Indeed, it is rarely listed in classifications of the causes of hemorrhage.² Nevertheless, hemorrhage as a complication of nephritis and uremia has been familiar to clinicians since the days of Richard Bright (1827). Epistaxis and retinal and cerebral hemorrhages are often observed. In a review of the hemorrhagic manifestations sometimes seen in nephritis, Riesman³ also listed metrorrhagia, hemoptysis, hematemesis, and hemorrhage into the ear. Mucosal hemorrhages in the gastrointestinal tract in cases of uremia were reported at autopsy in 52.9% of 136 cases by Jaffe and Laing⁴ and in 21.1% by Mason.⁵ These mucosal hemorrhages are the commonest digestive tract lesions seen in uremia. Hemorrhagic pleurisy and pericarditis may occur. Mediastinal hemorrhage has been reported.^{5a} Jaffe and Laing⁴ mention also hemorrhages in the epicardium, lung, mucosa of the renal pelvis, urinary bladder, uterus, and vagina. Six of their patients showed so many petechiae of the skin that the diagnosis on admission suggested a blood dyscrasia. Generalized purpura involving the skin and mucous membranes is seen occasionally as a terminal sign in uremia. Riesman³ reported two such cases. Davidson⁶ observed three instances of purpura in chronic interstitial nephritis associated with marked elevations of blood urea levels, reported as 245, 360, and 428 mg. per 100 cc.

Streicher⁷ produced a uremia-like condition in dogs by the slow intravenous injection of large amounts of

urea and observed a congested and hemorrhagic intestinal mucosa. Bollman and Mann⁸ produced hemorrhagic lesions in the stomach that were associated with marked elevations of blood urea levels by transplantation of the ureters into the intestine of dogs.

The mechanism of the hemorrhagic state occurring in uremia has never been clearly elucidated. Vascular degeneration and hypertension are not necessary factors. In a consideration of the possible role of arteriosclerotic changes in the intestinal tract as a basis for the hemorrhages in uremia, Jaffe and Laing⁴ found that vascular necrosis was always in close proximity to the necrosis of the mucosa and was never observed during the congestive or hemorrhagic stage of the lesions. The vascular necrosis was distinctly inflammatory and thus undoubtedly secondary, as is seen commonly in bacillary dysentery.

Schoenemann⁹ reported the postmortem observation in persons with nephritis of numerous superficial hemorrhages into the nasal mucosa. The capillaries near the

Fig. 2.—Photograph of a portion of the surface of the right lobe of the liver, showing the site of needle puncture and superficial scratching of the liver capsule.

epithelial surface were increased in number and in many cases had broken through the basement membrane, the capillary loops having forced their way through the basal epithelial cells. The capillary walls appeared normal, and the deeper vessels showed no degenerative changes. These

changes were not observed in diseases other than nephritis. Riesman³ suggested that the changes were due to a circulating substance that weakened the capillary walls and surrounding structures.

Jaffe and Laing,⁴ in their studies of the digestive tract in uremia, could detect no alterations of the walls of the capillaries or small veins, except for extreme dilatation of these vessels in contrast to narrow arterioles and small arteries. They suggested that the hemorrhages might be the result of disturbances in the innervation of the terminal vascular bed. They said that the increased permeability that is associated with the extreme widening of the small blood vessels leads first to edema and later to hemorrhages. Ulceration was attributed to bacterial invasion of the devitalized hemorrhagic areas.

No consistent coagulation defect has been demonstrated in the reported instances of uremic hemorrhage. Boyd¹⁰ states that there is a curious tendency toward hemorrhages in uremia for no apparent reason and that there is no satisfactory explanation beyond the vague suggestion of some toxic action on the vessel walls. Moore¹¹ states that the purpura of uremia has never been adequately explained and suggests that, since it is known that there is material damage to the liver in uremia, hypoprothrombinemia may be a cause. Atchley¹² reports that an elevated prothrombin time has been observed in a number of uremic patients at the Presbyterian Hospital in New York who showed hemorrhagic tendencies. On the other hand, Fishberg¹³ and Allen¹⁴ state that the coagulation time of the blood is usually increased in uremia. Davidson⁶ found no reduction in the number of platelets in two out of three cases in which examinations were made. A decreased capillary resistance in some cases of chronic renal disease has been reported.¹⁵

It is apparent that a study of hemostasis in uremia is needed. A consideration of the studies of Streicher,⁷ Schoenemann,⁹ and Jaffe and Laing⁴ leads to the conjecture that an increase in capillary fragility may prove to be a clinically demonstrable defect in uremic patients. Capillary fragility was not determined in the case reported above. Had it been determined and found appreciably increased, the needle biopsies would not have been performed. Since this experience, it has been my invariable practice to add the capillary fragility determination to the bleeding, clotting, clot retraction, and prothrombin times done prior to needle biopsy. A few instances have been found, in the absence of uremia, in which increased capillary fragility seemed to contraindicate biopsy, although other tests of hemostasis were normal.

SUMMARY

In a case of uremia, hemorrhages followed nonlacerating needle biopsies of liver and kidney. Needle biopsy may be contraindicated in some instances of uremia.

USE OF A TILT-TABLE IN EARLY REHABILITATION OF PARAPLEGIC PATIENTS

Samuel Climo, M.D., New Haven, Conn.

In discussing the prophylaxis of decubitus ulcers in paraplegic patients, it must be admitted that the ulcers develop in patients in every hospital regardless of size and over-all efficiency. The earlier the patient leaves his bed and avoids or reduces the complications of prolonged immobilization, namely, bedsores, decalcification of bones, and genitourinary infections, the better are his chances for rehabilitation, both occupational and psychological. The opportunities for rehabilitation are made available early by the use of a modified, four-wheeled stretcher that is capable of securing and maintaining the paraplegic patient in the erect posture (see figure) as soon as the medical status permits.

A patient can remain strapped in the erect position for many hours, since the plantar integuments, composed of highly specialized tissue, are capable of withstanding prolonged pressure from body weight. Thus, a patient can engage in skillful occupation. Since the table rotates

A, modified four-wheeled stretcher with the top tilted vertically and, B, patient strapped to the top and tilted.

from a horizontal position to a vertical one, any intermediate incline can be used for resting, even sleep. The displacement of floor space by the converted table does not exceed appreciably that of the ordinary wheelchair.

The tilt-table is not available yet commercially. The ordinary four-wheeled stretcher can be converted in any institutional workshop. The horizontal top of the stretcher can be removed and the width of the frame increased to permit the top to rotate on a horizontal axis. Placing the axis off center permits the top to rotate through an angle approximating 90 degrees to the floor. When the tilt-table is in the vertical position, the broad footrest terminates just above the level of the floor. Quarter gears are welded on the underside of the top to rotate on a pivoting axis. A simple gear-locking mechanism is employed to maintain the incline at any level.

COUNCIL ON PHARMACY AND CHEMISTRY

NEW AND NONOFFICIAL REMEDIES

The following additional articles have been accepted as conforming to the rules of the Council on Pharmacy and Chemistry of the American Medical Association for admission to New and Nonofficial Remedies. A copy of the rules on which the Council bases its action will be sent on application.

R. T. STORMONT, M.D., Secretary.

Histamine Phosphate-U.S.P.—The structural formula of histamine phosphate may be represented as follows:

Actions and Uses.—Histamine exists in various organs and tissues of the body, probably in an inert form. It produces local vasodilatation when released from the cell under appropriate stimuli, such as trauma, shock, and possibly allergic reactions. When injected into an animal, histamine stimulates gastric secretion and produces flushing, nausea, bronchospasm, fall in blood pressure, arrhythmia, and gastrointestinal contraction. It acts directly on the receptive substance in smooth muscle.

Histamine, although absorbed orally, produces highly variable effects when administered by this route. Salts of histamine are usually administered subcutaneously, intravenously or intramuscularly.

Histamine phosphate is employed as a test for gastric secretory activity. It also produces temporary benefit in some patients with Ménière's syndrome, including those showing sudden deafness. It has been used in the treatment of multiple sclerosis; although the effects are equivocal, they deserve further study. Some patients apparently experience temporary amelioration of the disease after histamine therapy.

Although histamine has been recommended for treatment of migraine and certain cephalgias, the evidence of value is not convincing. Because of the known hazards of histamine therapy, the drug should not be used indiscriminately in these conditions.

Histamine is a potent drug, and overdosage or administration to susceptible persons may give rise to serious reactions. Vasomotor collapse, shock, and even death may occur quickly if the drug is administered too rapidly or in too great a quantity. Thus, when calculating dosages, it should be remembered that the salt contains only about 36% of the active base. Epinephrine hydrochloride is the antidote of choice in histamine overdosage and should be given intramuscularly or, in severe poisoning, intravenously. A solution of epinephrine hydrochloride 1:1,000 should always be readily available at the time histamine is administered.

Dosage.—For the treatment of Ménière's syndrome and multiple sclerosis, a slow intravenous injection of histamine phosphate, 1.1 mg. per 100 cc., in isotonic sodium chloride solution may be administered. The initial rate of administration should not exceed 20 to 30 drops per minute and should never exceed 50 to 60 drops per minute. A maximum of 250 cc. of such a solution may be administered in not less than 90 minutes. The therapy may be repeated daily until improvement is noted or until it is determined that the patient will not respond.

Any reaction should be treated immediately with the intramuscular or intravenous injection of 1:1,000 epinephrine hydrochloride.

Don Baxter, Inc., Glendale, Calif.

Solution Histamine Phosphate: 250 cc. Vacoliter bottles. A solution in isotonic sodium chloride containing 1.1 mg. of histamine phosphate in each 100 cubic centimeters.

Trihexyphenidyl Hydrochloride.—Artane Hydrochloride (Lederle).— $\text{C}_{20}\text{H}_{21}\text{NO}\cdot\text{HCl}$.—M.W. 337.92.—3-(1-Piperidyl)-1-phenyl-1-cyclohexyl-1-propanol hydrochloride.—The structural formula of trihexyphenidyl hydrochloride may be represented as follows:

Actions and Uses.—Trihexyphenidyl hydrochloride, a synthetic piperidyl compound, exhibits an atropine-like action and exerts an antispasmodic effect on smooth muscle and an inhibitory action on the parasympathetic nervous system. Thus, spasm of smooth muscle is relieved by direct action and by indirect parasympathetic release. The drug also relieves spasticity of voluntary muscle, partly because of its parasympatholytic action and partly because of action on the cerebral motor centers. Unlike atropine, the action of trihexyphenidyl is strongest in producing desirable, relaxant effects and weakest in producing undesirable side-effects. Compared with atropine, trihexyphenidyl produces about one-half as intense antispasmodic action, one-third as great mydriatic action, one-eighth as much antialagogue effect, and one-tenth as much cardiovagal inhibition.

Trihexyphenidyl hydrochloride is useful for the treatment of all forms of parkinsonism, including the postencephalitic, arteriosclerotic, and idiopathic types. It reduces the muscular rigidity and relieves the depression and mental inertia characteristic of this syndrome. The drug is especially effective in reducing the rigidity produced by muscle spasm, thus increasing the ability of the patient to achieve coordination of muscular motions. Tremor is usually reduced, but in some patients who have been severely spastic, it may become more perceptible as spasticity is relieved. Sialorrhea is reduced, but with less accompanying mouth-dryness, blurred vision, or mydriasis than with the use of atropine. Trihexyphenidyl is particularly useful in the treatment of arteriosclerotic parkinsonism because, unlike atropine, it usually does not tend to precipitate glaucoma.

Trihexyphenidyl hydrochloride thus far has seldom produced severe reactions with therapeutic dosages. Some patients experience minor side-effects such as dryness of the mouth, blurring of vision, dizziness, mild nausea, or nervousness. Compared with the symptoms of unrelieved parkinsonism, they are usually not troublesome and may be controlled by adjustment of dosage or time of administration. These side-effects tend to decrease with continued use of the drug. The infrequent but more severe reactions of mental confusion, agitation, or nausea with vomiting tend to occur in arteriosclerotic patients or in persons exhibiting other drug idiosyncrasies. Such patients must develop tolerance to the drug gradually, beginning with a smaller initial dose and increasing the dosage more slowly until an effective level is reached. If a severe reaction occurs, administration of the drug should be discontinued temporarily for several days and then resumed at a lower dosage level. Hypertension or cardiac, liver, or kidney disorders do not contraindicate use of the drug, but patients with these conditions should be carefully observed.

Dosage.—Trihexyphenidyl hydrochloride is administered orally. The usual initial dose is 1 mg. for the first day. If the patient is already receiving treatment with other agents, this initial dose should be substituted for a part of the current therapy. As the dosage of trihexyphenidyl is gradually increased, other medication should be decreased until the drug has replaced the former treatment or until an effective balance has been achieved. With prior therapy and in arteriosclerotic or sensitive patients, daily increments of the dose should be small until satisfactory tolerance is attained. If prior medication or unusual reactivity is not involved, the dosage is increased to 2 mg. for the second day, with subsequent increments of 2 mg. daily until a total daily amount of 6 to 16 mg. is reached. Postencephalitic patients may require as much as 12 to 15 mg. daily. At the lower level of daily dosage, the total amount can be divided into three equal parts, taken near meal times; at a higher level, a fourth dose at bedtime is required. Patients are allowed to choose whether to take the medication before or after meals. Postencephalitic patients, who have more excessive

Dr. Robert Wells Lippman

salivation, will prefer administration after meals and may require small doses of atropine sulfate as an adjuvant. Whenever the mouth becomes excessively dry, the drug can be taken before meals unless this causes nausea; if it is necessary to administer the dose after meals, dryness can be allayed by hard candy, gum, or extra intake of fluid.

Tests and Standards.—

Physical Properties: Trihexyphenidyl hydrochloride is a white, odorless solid, m.p. 249.0-249.5° (with slight decomposition). It is freely soluble in methanol, and very slightly soluble in ether and in benzene. The approximate amounts which dissolve at 25° in the following solvents to form 100 ml. of solution are: 6 gm. in alcohol, 5 gm. in chloroform, and 1 gm. in water. The pH of a 1% solution is 5.5-6.0.

Identity Tests: Dissolve about 50 mg. of trihexyphenidyl hydrochloride in 25 ml. of water. To 5 ml. of the solution add dropwise a saturated aqueous solution of picric acid; a yellow precipitate forms. To another 5 ml. portion add 1 ml. of diluted nitric acid and 1 ml. of silver nitrate T.S.; a white precipitate forms which is soluble in excess ammonia T.S. (presence of chloride). To another 5 ml. portion of the solution add 1 ml. of diluted hydrochloric acid and 2 ml. of potassium ferrocyanide T.S.; a light green precipitate forms on standing. To another 5 ml. portion add dropwise 0.1 N sodium hydroxide; a white precipitate forms.

Transfer to a 50 ml. volumetric flask 25 mg. of trihexyphenidyl hydrochloride, fill to the mark with 0.1 N hydrochloric acid, and mix. Measure the absorbancy in a 1 cm. quartz cell, using 0.1 N hydrochloric acid as a blank. The solution exhibits ultraviolet absorption maxima at about 252 and 257 m μ , a minimum at about 254 m μ , and a point of inflection at about 262 m μ .

Purity Tests: Dry about 1 gm. of trihexyphenidyl hydrochloride, accurately weighed, at 105° for 4 hours; the loss in weight is not more than 2.0%.

Char about 0.4 gm. of trihexyphenidyl hydrochloride, accurately weighed, over a low flame, cool the residue, add 1 ml. of sulfuric acid, heat cautiously until evolution of sulfur trioxide ceases, ignite, cool, and weigh; the residue does not exceed 0.05%.

Assay: (Trihexyphenidyl Hydrochloride) To prepare a standard, recrystallize the trihexyphenidyl hydrochloride as follows. To 5 ml. of a saturated solution of trihexyphenidyl hydrochloride in methanol add petroleum ether slowly with vigorous stirring until precipitation is complete. Filter through a fritted glass filter, and wash the precipitate with three 5 ml. portions of a 1:1 mixture of methanol and petroleum ether. Repeat the recrystallization and dry in a vacuum over phosphorus pentoxide at room temperature for 24 hours. Dissolve 0.1 gm. of the recrystallized trihexyphenidyl hydrochloride, accurately weighed, in 5 ml. of methanol. Transfer the solution to a 100 ml. volumetric flask, fill to the mark with water, and mix. Transfer to separate 100 ml. beakers 3, 5, 10, and 15 ml. of the solution. Add 1 ml. of methanol and enough water to dilute the solutions in each beaker to 20 ml. Add 6 ml. of freshly prepared 2% ammonium reineckate in methanol. Heat on a steam bath about 30 seconds. Cool to room temperature with intermittent swirling to induce crystallization. If crystallization does not occur on cooling, reheat the solution. Refrigerate the mixture for 2 hours and filter with suction, collecting the precipitates in fritted glass funnels. Wash the precipitates with 5 ml. portions of ice-cold water until the filtrates are colorless. Place test tubes under the stems of the funnels in the suction flasks, and, with the aid of suction, wash the precipitates into the test tubes with 2 ml. portions of acetone until the precipitates are entirely dissolved. Transfer the acetone solutions to 10 ml. volumetric flasks, fill to the marks with acetone, and mix. Spectrophotometrically determine the absorbancies in 1 cm. cells at 526 m μ , using acetone as a blank. Plot the absorbancies against concentrations to give a standard curve. Dissolve about 0.1 gm. of the trihexyphenidyl hydrochloride to be analyzed, accurately weighed, in 5 ml. of methanol. Transfer the solution to a 100 ml. volumetric flask, fill to the mark with water, and mix. Transfer to a 100 ml. beaker 10 ml. of the solution, add 1 ml. of methanol and 9 ml. of water, and proceed as before. Read the concentration of trihexyphenidyl hydrochloride from the standard curve. The amount of anhydrous trihexyphenidyl hydrochloride is not less than 98.0 nor more than 102.0%.

Dosage Forms of Trihexyphenidyl Hydrochloride

ELIXIRS, Identity Tests: To 100 ml. of the elixir add with stirring 50 ml. of ammonia T.S. and allow the mixture to stand for 30 min. Using suction, filter the mixture through a fritted glass filter funnel. Wash the precipitate with three 5 ml. portions of water. Place a test tube under the stem of the funnel in the suction flask and, with the aid of suction, wash the precipitate into the test tube with five 3 ml. portions of 0.1 N hydrochloric acid. Transfer the solutions to a 50 ml. volumetric flask, fill to the mark with 0.1 N hydrochloric acid, and mix. The solution responds to the spectrophotometric identity test for the active ingredient in the monograph for trihexyphenidyl hydrochloride.

Assay: (Trihexyphenidyl Hydrochloride) Transfer to a 125 ml. Erlenmeyer flask a volume of elixir, accurately measured, equivalent to about 10 mg. of trihexyphenidyl hydrochloride, add 10 ml. of diluted hydrochloric acid, and proceed with the spectrophotometric assay as directed in the monograph for trihexyphenidyl hydrochloride starting with, "Add 6 ml. of freshly prepared 2% ammonium reineckate in methanol." The amount of trihexyphenidyl hydrochloride is not less than 95.0 nor more than 105.0% of the labeled amount.

(Alcohol) To 100 ml. of elixir add 100 ml. of water and on the solution run a U. S. P. alcohol determination. The amount of alcohol is not less than 90.0 nor more than 110.0% of the labeled amount.

TABLETS, Identity Tests: Powder a number of tablets equivalent to about 25 mg. and triturate the powder with 10 ml. of 0.1 N hydrochloric acid. Transfer the mixture to a 15 ml. centrifuge tube and centrifuge for 10 min.

at about 2,500 rpm. With the aid of suction, filter the supernatant liquid through a fritted glass filter funnel into a test tube placed under the stem of the funnel in the suction flask. Add 10 ml. of 0.1 N hydrochloric acid to the centrifuge tube, break up the residue at the bottom of the tube, and stir thoroughly. Centrifuge the mixture again and filter the supernatant liquid. Transfer the filtrate to a 50 ml. volumetric flask, fill to the mark with 0.1 N hydrochloric acid, and mix. The solution responds to the spectrophotometric identity test for the active ingredient in the monograph for trihexyphenidyl hydrochloride.

Assay: (Trihexyphenidyl Hydrochloride) Weigh 20 tablets and powder them. Transfer to a 50 ml. centrifuge tube an amount of powder, accurately weighed, equivalent to about 20 mg. of trihexyphenidyl hydrochloride. Add 5 ml. of water and heat in a steam bath for 30 min., stirring the mixture until the powder is thoroughly wetted. Remove the mixture from the bath, add 15 ml. of methanol, and stir the mixture until it is thoroughly wetted. Place the tube in a steam bath, stir the mixture continuously, and allow the methanol to boil vigorously about 2 minutes. Centrifuge the mixture for 5 minutes at about 3,000 rpm. Pour the supernatant liquid into a 250 ml. beaker containing several glass beads. Repeat the extraction with four additional 15 ml. portions of methanol. Evaporate the combined methanol extracts to about 5 ml. and add 20 ml. of water. Transfer the solution to a 50 ml. volumetric flask, fill to the mark with water, and mix. Transfer 20 ml. of this solution to a 100 ml. beaker and proceed with the spectrophotometric assay as directed in the monograph for trihexyphenidyl hydrochloride starting with, "Add 6 ml. of freshly prepared 2% ammonium reineckate in methanol." The amount of trihexyphenidyl hydrochloride is not less than 95.0 nor more than 105.0% of the labeled amount.

Lederle Laboratories Division, American Cyanamid Company, Pearl River, N. Y.

Elixir Artane Hydrochloride: 473 cc. and 3.78 liter bottles. A flavored elixir containing 0.5 mg. of trihexyphenidyl hydrochloride in each cubic centimeter. Preserved with 0.08% methylparaben and 0.02% propylparaben.

Tablets Artane Hydrochloride: 2 and 5 mg. U. S. trademark 500,574.

Testosterone-U.S.P.—Androlin (Lincoln).—C₁₉H₂₈O₂.—M.W. 288.41.—The structural formula of testosterone may be represented as follows:

Actions, Uses, and Dosage.—Testosterone in aqueous suspension apparently has a slightly lesser intensity and slightly greater duration of androgenic action than testosterone propionate. See monograph on testosterone propionate in N. N. R.

Tests and Standards.—

Dosage Forms of Testosterone

SUSPENSIONS, Identity Tests: Filter through a fritted glass funnel of fine porosity an amount of suspension equivalent to about 0.15 gm. of testosterone. Wash the residue with two 10 ml. portions of water and dry in a vacuum desiccator over phosphorus pentoxide. The residue responds to the U. S. P. identity tests for testosterone.

Assay: (Testosterone) Transfer to a fritted glass funnel of fine porosity an amount of suspension, accurately measured, equivalent to about 0.15 gm. of testosterone. Remove the suspending medium with gentle suction and wash the residue with three 10 ml. portions of water. Quantitatively transfer the testosterone to a 100 ml. volumetric flask by dissolving the residue in 25 ml. of alcohol and washing the funnel thoroughly with five 10 ml. portions of alcohol. Fill the flask to the mark with alcohol, and mix. Transfer to a second 100 ml. volumetric flask 10 ml. of this solution, fill to the mark with alcohol, and mix. Transfer to a third 100 ml. volumetric flask 5 ml. of this last solution, fill to the mark with alcohol, and mix. Spectrophotometrically determine the absorbancy in a 1 cm. quartz cell at 241 m μ , using alcohol as a blank. The concentration of testosterone in the solution in mg./ml. = absorbancy $\div$ 54. The amount of testosterone is not less than 90.0 nor more than 110.0% of the labeled amount.

Bio-Intrasol Laboratories, Inc., Brooklyn.

Aqueous Suspension Testosterone with Procaine Hydrochloride 1%: 10 cc. vials. A suspension containing 25 or 50 mg. of testosterone in each cubic centimeter. Preserved with thimerosal 1:10,000.

Lincoln Laboratories, Inc., Decatur, Ill.

Aqueous Suspension Androlin: 10 cc. vials. A suspension containing 25 or 50 mg. of testosterone in each cubic centimeter. Preserved with thimerosal 1:10,000.

Metropolitan Laboratories, Inc., Oyster Bay, N. Y.

Aqueous Suspension Testosterone with Benzyl Alcohol 2%: 10 cc. vials. A suspension containing 10, 25, 50 or 100 mg. of testosterone in each cubic centimeter.

COUNCIL ON PHYSICAL MEDICINE AND REHABILITATION

APPARATUS ACCEPTED

The following additional product has been accepted as conforming to the rules of the Council on Physical Medicine and Rehabilitation of the American Medical Association for inclusion in Apparatus Accepted. A copy of the rules on which the Council bases its action will be sent on application.

RALPH E. DE FOREST, M.D., *Secretary.*

Bennett Pressure Breathing Therapy Unit, Model TV-2P

V. Ray Bennett and Associates, Inc., 320 S. Robertson Blvd., Los Angeles 48, Calif.

The Bennett Pressure Breathing Therapy Unit delivers oxygen under positive pressure to a patient but stops the flow when the pulmonary inflation reaches the point of diminished flow; in other words, it is said to be "flow-sensitive." When it is connected to a patient, a slight inspiratory effort on his part, which creates a very slight initial negative pressure of usually less than 1 cm. H₂O, starts the flow of oxygen into his airways. The pressure then builds up to that set by the control pressure adjustment, and the flow continues at whatever rate the lungs are expanding. The unit will continue to maintain this inspiratory phase until the flow rate is reduced to approximately one or two liters per minute or until the flow direction is reversed. This apparatus therefore differs from the "pressure-sensitive" regulators in which the flow continues until inflation results in a specified back-pressure.

Bennett Pressure Breathing Therapy Unit, Model TV-2P

The essential part about which the apparatus is built is the flow-sensitive Bennett valve, which is to be attached to a cylinder of compressed oxygen. The standard accessories are a mask, mask harness, test lung (a bag of about one liter capacity), nebulizer, wrench, screw driver, cleaning brush, and instruction manual. These are included in the shipping weight, which is 7.7 kg. (17 lb.). A carrying case is optional but the "Flex Arm" to support the connections is a standard part of the unit. Packed for ship-

ment the standard equipment makes a package measuring 26 by 55 by 25 cm. (10½ by 22 by 10 in.).

From sources acceptable to the Council evidence was obtained indicating that the apparatus was well made, that it worked as represented by the manufacturer, and that it was useful in the treatment of certain types of dyspnea and apnea and in the administration of aerosol therapy.

The Council on Physical Medicine and Rehabilitation voted to include the Bennett Pressure Breathing Therapy Unit, Model TV-2P with the stipulation that its use be limited to medical treatments under the direction of a qualified physician.

REPORT OF THE COUNCIL

The Council on Physical Medicine and Rehabilitation has authorized publication of the following article.

AN APPRECIATION

The Council on Physical Medicine and Rehabilitation expresses its gratitude and appreciation for the services of the following consultants, whose assistance in carrying out the work of the Council has been given so freely during 1953: Drs. Thomas D. Allen, Morton Andelman, Thomas L. Ball, Robert W. Benson, Conrad Berens, Theodore B. Bernstein, William Bierman, Edward Bigg, Lester Blum, Ben L. Boynton, Rowine Brown, Raymond Carhart, Mrs. Eva Thompson

Carson, Drs. Milton B. Cole, H. G. Davis, Jr., G. deTakats, Donald J. Erickson, David C. Fainer, Alan R. Feinberg, Theodore Friedemann, T. C. Galloway, Clarence J. Gamble, Aram Glorig, Stacy R. Guild, William F. Hamilton, Opal E. Hepler, John S. Hibben, Howard P. House, John W. Huffman, I. F. Hummon, Ernest E. Irons, V. J. Jacey, Richard P. Jahn, Martin H. Kalser, Mary Karp, M. E. Knapp, A. B. C. Knudson, M. M. Kunde, Edward H. Lambert, Ludwig G. Lederer, Alfred Lewy, Edward M. Litin, Douglas Macfarlan, Robert P. MacFate, Raymond W. McNealy, Sedgwick Mead, C. O. Molander, Fred B. Moor, Lester A. Nalefski, Elliot V. Newman, Louis B. Newman, Benjamin H. Orndoff, Mr. H. W. Pavela, Drs. L. W. Peterson, Gerald H. Pratt, James W. Rae, Mr. Luther G. Ramer, Drs. Arthur A. Rodriguez, Max S. Sadove, Oscar A. Sander, D. E. Sanders, Robert S. Schwab, Martin H. Seifert, John K. Sokol, Ralph W. Taraba, Vernon C. Turner, Albert Vanderkloot, H. O. Wernicke, Jessie Wright, and Mr. L. D. Williams.

The following persons have rendered valuable services as members of Advisory Committees:

American Health Resorts.—Drs. F. A. Hellebrandt, M. B. Jarman, Walter S. McClellan, and Euclid M. Smith.

Artificial Limbs.—Drs. Rufus H. Alldredge, Henry H. Kessler, Paul E. Klopsteg, and Eugene E. Record and Messrs. Chester Haddan and J. B. Korraday.

Audiometers and Hearing Aids.—Drs. Richard K. Cook, Kenneth M. Day, Harvey Fletcher, Edmund P. Fowler, Gordon D. Hoople, M. H. Lurie, C. Stewart Nash, and S. Richard Silverman.

Education.—Drs. Robert L. Bennett, Jr., Earl C. Elkins, H. Worley Kendell, Frederic J. Kottke, Donald L. Rose, and Walter M. Solomon.

Electrocardiographs.—Drs. George Fahr, Harold Feil, Harold E. B. Pardee, and William D. Stroud.

Electroencephalography.—Drs. P. Bailey, Edward J. Baldes, Hallowell Davis, Frederic A. Gibbs, Franc D. Ingraham, and Herbert H. Jasper.

Ionizing Radiations.—Drs. Richard Hall Chamberlain, Edwin C. Ernst, E. R. Newell, and Edith H. Quimby and Lauriston S. Taylor.

Ophthalmic Devices.—Drs. David G. Cogan, William F. Hughes, Jr., K. N. Ogle, W. C. Owens, and K. C. Swan.

Respirators.—Drs. Edward L. Compere, Archer S. Gordon, William T. Green, Warren E. Wheeler, James L. Whittenberger, and James L. Wilson.

Sterility and Fertility.—Drs. William J. Dieckmann, Walter J. Meek, and Pendleton Tompkins and Mr. R. R. Olin.

COUNCIL ON FOODS AND NUTRITION

ACCEPTED FOODS

The following product has been accepted as conforming to the rules of the Council.

JAMES R. WILSON, M.D., *Secretary.*

Prince Macaroni Manufacturing Company, Lowell, Mass.

Spinach Pastina

Ingredients: Fancy durum wheat flour, dehydrated spinach, thiamine, riboflavin, niacin, and iron phosphate.

Analysis (submitted by manufacturer).—Total solids 89.5%, moisture 10.5%, ash 1.22%, fat 1.68%, protein (N × 5.7) 12.9%, crude fiber 0.55%, and carbohydrates other than crude fiber (by difference) 73.12%.

Vitamins and Minerals	Mg. per Hundred Grams
Thiamine.....	0.9
Riboflavin.....	0.4
Niacin.....	5.9
Calcium.....	63
Phosphorus.....	173
Iron.....	4.8

Calories.—3.7 per gram; 105 per ounce.

Use.—In the feeding of infants and older children.

BUILDING THE PROGRAM FOR THE SCIENTIFIC ASSEMBLY

Few members of the American Medical Association who have not had experience in planning programs for large scientific meetings, such as are provided each year at the A. M. A. Annual Meeting in June, are fully cognizant of the time factor essential in the organization of a successful scientific session. Over a long period of years, the Council on Scientific Assembly, which has charge of the program, has evolved with the aid of the Director of Scientific Exhibits, the Secretary of the American Medical Association, and other personnel at the headquarters office in Chicago, a time schedule necessary for the smooth functioning of a somewhat complicated evolutionary process.

Plans for the Annual Meeting usually begin a year in advance, at which time new officers of the various sections are elected or old officers retain their posts. By September the secretary of each section begins to think in terms of the program for the following June meeting, and subjects for consideration are accepted by him from the members of the American Medical Association as early as Labor Day. By mid-October the general outline of a section program is usually well advanced, and at that time the section secretary, and sometimes the section representatives to the Scientific Exhibit, meet in Chicago with the Council on Scientific Assembly and the Director of the Scientific Exhibit and his staff, to consider the program as a whole. Each secretary presents to the Council and to his brother secretaries an outline of his proposed program. At that time, joint meetings are usually arranged and panel discussions or symposiums are given consideration.

More active work on the program takes place between mid-October and mid-December, so that, soon after the first of the year, a secretary ordinarily has his program practically complete. The final arrangements are undertaken during the month of January and the first two weeks of February, the closing date usually being set for February 15. To many members of the American Medical Association this date, four months in advance of the Annual Meeting, seems early, but it is necessary to adhere to it so that the preliminary program can be submitted for publication in THE JOURNAL about April 10. At the same time, the chairman of the Council on Scientific Assembly, with the assistance of the mem-

bers, makes up the program for the General Scientific Meeting. This ordinarily consists of nine presentations by invitation, the aim being to present to the members of the American Medical Association as a whole a summary of the current advances in medicine by the leaders of the profession. This program too is completed by February 15, so that it may also appear in the Convention Number of THE JOURNAL.

It is frequently desirable to combine a paper presented at a section meeting or before the General Scientific Meeting with an exhibit on the same subject in the Scientific Exhibit. The time relation for applications for space in the Scientific Exhibit is about the same as for papers to be read in the Scientific Assembly. Application forms for requirements must be filed with the Director of Scientific Exhibits at A. M. A. headquarters early in January. Prior to that time, it is also desirable for a member wishing to arrange an exhibit to consult with the section representative, so that exhibits may be coordinated with others on similar subjects and assigned to the appropriate section.

The essential basis for good scientific assembly at an Annual Meeting depends on the coordination between the General Scientific Meeting program; the section program; the Scientific Exhibit; the motion pictures; the presentations associated with exhibits, such as those given in relation to fractures, diabetes, or other aspects of medicine; and more recently the color television program, which has become such an indispensable part of the Scientific Assembly. To coordinate all this requires a continual overseeing the year round by the Council on Scientific Assembly, which also has under its jurisdiction the program for the Clinical Meeting held each December.

The Clinical Meeting presents programming problems of a different type. There are no section meetings and no General Scientific Session similar to those held at the annual meeting. There are, however, Scientific Exhibits, motion pictures, and color television. The program ordinarily consists of a series of clinical presentations to small groups, and the arrangements for its details fall largely on the chairman of the local committee on arrangements and on the chairman of the local program committee. The chairman of the local committee on arrangements, selected locally, is appointed by the Board of Trustees prior to the time of the Clinical Meeting occurring a year in advance of the one in which he is to take charge. This is done so he can attend that meeting and confer with the previous chairman of the local committee on arrangements and with the members of the Council on Scientific Assembly. Thus, from year to year a continuity of effort is established that leads to continued improvement in the character of the Clinical Meeting. Because of the nature of the program and the particular knowledge that the local chairman is likely to have about his own city and the general area where the meeting is to be held, most of the speakers are invited to participate rather than being chosen from applications from the general membership of the American Medical Association. Such applications, however, may be made to the chairman of the local committee on arrangements for the consideration of his program committee. These should be in his hands by May of the year in which the meeting is to be held, so that they can be given considera-

tion when the Council on Scientific Assembly meets with the chairman of the local committee in that month. The same time schedule, moreover, applies to applications for the Scientific Exhibit.

EMPLOYMENT FOR DIABETICS

The American Diabetes Association has emphasized its philosophy that a controlled diabetic is a good employment risk. Also, by virtue of his capability of performing a full day's work satisfactorily despite his disease, the diabetic should not be classed with the physically handicapped. During the past five years, the association, through its committee on employment, has endeavored to reach some unanimity of opinion in the formulation of recommendations to labor and management regarding the industrial utilization of the diabetic.¹ The structure of the committee is of interest, for extramural members were sought from the United States Civil Service Commission, the United Mine Workers of America, the Industrial Hygiene Foundation, and the diabetes section of the Public Health Service. There was additional contact with the Office of Vocational Rehabilitation of the Federal Security Agency and with the Association of Railroad Engineers.

Mildly diabetic persons, in no need of insulin, present no employment problem. Of persons with severe diabetes, with both insulin and regulated-diet needs, there is the well-controlled and well-regulated patient and the uncooperative and poorly regulated patient. The latter, if hired, would prejudice employers against all diabetics, for they not only are poor work risks because of their diabetes but are potential absentees in the light of complications to come. The well-controlled diabetic has proved his worth and his employment stability in hundreds of organizations employing such persons. Standards suggested by the committee for both employers and prospective workers with diabetes, in essence, are these: 1. A diabetic seeking employment should present a note from his physician stating that he is controlled and undergoes periodic examinations. 2. Diabetics can perform any work for which they are equipped physically, mentally, and educationally. Those taking insulin in large doses should not be assigned to work wherein hypoglycemic attacks would injure either them or others. 3. Diabetics should work straight shifts (unbroken and nonrotating). If a rotating shift is necessary, they should avoid the midnight to 8 a. m. schedule. This is the only concession in terms of hours that a well-controlled diabetic should ask. 4. Certain key personnel in a plant employing diabetics should be familiar with the nature of diabetes and the possibility of coma or insulin reactions. 5. Diabetics should carry cards or tags identifying their condition. 6. The plant physician, in cooperation with the diabetic employee's family physician, should perform periodic blood and urine examinations, if the patient's work schedule precludes visiting his regular laboratory facilities. 7. Each diabetic should have a complete annual physical examination. 8. Transfer or reassignment of a diabetic at the request of the plant physician, when new complications create new risks, is a justified procedure. 9. An insulin-requiring diabetic is considered controlled if his fasting blood sugar is not below normal limits and not over 150

mg. per 100 cc. (Folin-Wu method), if the level after a meal is not higher than 250 mg. per 100 cc., and if he is under regular medical supervision.

It is to be pointed out that excellent liaison has been established by the committee at the national level with the Congress of Industrial Organizations, the American Federation of Labor, and the Railroad Brotherhoods. If necessary this cooperation can be extended downward. With these employment standards in realistic usage by employers and personnel directors, the diabetic applicant should be considered just as eligible for work as the nondiabetic candidate. His effective contribution to industry has been demonstrated, and with continuing co-operative efforts among labor, employers, and professional groups toward hiring the diabetic, employment prejudice will continue to abate.

ILLEGAL OPERATION OF MEDICAL DIATHERMY APPARATUS

The Federal Communications Commission which renders great public service, released recently an interesting and timely public notice, which is of great importance to many physicians. It points out the hazards involved in the illegal operation of medical diathermy apparatus now in use. An abstract of this public notice appears elsewhere (page 1026) in this issue of THE JOURNAL. The commission has set forth the very important reasons for its 1947 ruling, which assigned certain specific frequencies for the exclusive use of medical and industrial diathermy equipment and which gave users of such equipment until June 30, 1952, to acquire apparatus that conformed to the commission's rules. In 1952, the Council on Physical Medicine and Rehabilitation of the American Medical Association petitioned the commission to extend this time limit. The commission did extend the deadline until June 30, 1953, thus giving users a total of six years to comply.

FCC type-approved medical diathermy apparatus manufactured since 1947 is designed to minimize interference with radio communications for home reception, police and fire departments, airlines, airplane landing systems, radio-directed missiles, and television. Excessive radiation from nonconforming diathermy apparatus could be used by enemy aircraft as a navigation aid in flying to target areas in the United States.

Articles in the Council on Physical Medicine and Rehabilitation columns and other articles published in THE JOURNAL since 1947 have called the profession's attention to FCC rules for medical diathermy apparatus. Users of nonconforming medical diathermy apparatus are urged once again to acquire apparatus that can be legally operated. For the information of the profession, the Council on Physical Medicine and Rehabilitation can provide a list of Council-accepted medical diathermy apparatus. This is an extremely important problem requiring the cooperation and understanding of all interested parties, particularly those persons who are using medical diathermy machines not meeting the requirements of the commission.

1. Employment of Diabetics: Statement of the Committee on Employment, American Diabetes Association, July, 1952, *Diabetes* 1: 336 (July-Aug.) 1952. Beardwood, J. T., Jr.: Employment [of Diabetics], *ibid.* 2: 334 (July-Aug.) 1953.

ORGANIZATION SECTION

TEXAS MEDICAL ASSOCIATION

The Texas Medical Association, which in September, 1952, celebrated its approaching centennial with the dedication of its new memorial library and headquarters building in Austin, was founded Jan. 17, 1853. The 35 physicians who assembled in response to the call "To all regular authorized Physicians of the State of Texas" adopted a constitution and bylaws that included provision for the formation of subordinate societies, the first of which, the Bexar County Medical Society, was chartered in September of that year. After the second assembly of the state association, Nov. 14, 1853, there is an unexplained period in which no meetings were held until 1869 when at a meeting in Houston the body was reorganized as the Texas State Medical Association. In April, 1901, a new charter was issued in the name of the State Medical Association of Texas, a title that was retained until 1951, when the original appellation was resumed.

The headquarters, too, changed frequently through the years, the first building to house offices of the association being the Fort Worth National Bank Building, where headquarters were maintained until 1910. There followed a succession of rented "homes" in the Continental Bank Building, the Western National Bank Building, the Newby Building, and the Medical Arts Building until 1935, when the residence at 1404 West El Paso Street was

Texas Medical Association memorial library and headquarters.

purchased for the central office. In 1948, headquarters were transferred to Austin, where a three story Victorian residence was leased at 700 Guadalupe Street.

The present site at Lamar Boulevard and 19th Street was given to the association by the Travis County Medical Society, and a bequest of \$50,000 provided for in an irrevocable trust by Dr. and Mrs. Sam E. Thompson of Kerrville assured the association of the necessary funds for building and operating the library. The auditorium-lounge of the new central office and library building have been named in honor of Dr. Thompson, an emeritus member, who served the state association as president, as member and for 10 years chairman of its board of trustees, and as its delegate to the American Medical Association for 12 years. The Sam Thompson lounge-auditorium, with a seating capacity of 300, in which executive council and other conferences are held, and the library occupy the first floor of the granite-trimmed limestone structure. The library, which has more than 22,000 bound and unbound items, maintains a package service including about 375 periodicals, 7,000 books, 156,000 reprints, 150 professional films, and 50 films suitable for lay audiences. The second floor houses the offices for executive, business, medical services, and public relations activities, as well as those of the state advisory committee, the woman's auxiliary, and the *Texas State Journal of Medicine*, which was founded in July, 1905. Complimentary subscriptions are being provided for senior students of the medical colleges in Texas, at which the association also sponsors lectures and special Medical Students' Days. For graduates of these schools, as well as for other physicians, the association maintains an active placement service, and in furtherance of post-graduate education relays a series of panel discussions by telephone to country medical societies and hospital staffs throughout the state.

The association has long been active in sponsoring medical legislation. In 1907, through the efforts of its legislative committee, the one board medical practice act became a law. In 1917 the vital statistics bill was helped through the legislature, and a more effective workmen's compensation act was passed. Ten years later the association sponsored (1) an amendment to the medical practice act that empowered the board of medical examiners to require the annual registration of all the physicians of Texas and to collect an annual fee of \$2 and (2) a bill for reorganization of the state board of health. Still later a minimum standards bill was obtained.

The association has a membership of almost 6,700 physicians. Its woman's auxiliary, which, founded in 1918, was instrumental in establishing an auxiliary in the American Medical Association in 1922, numbers about 4,500 members, whose annual meeting is concurrent with that of the state association. The annual sessions rotate among Dallas, Fort Worth, Galveston, Houston, and San Antonio, where the convention will be held this year May 3-5 under the presidency of Dr. George Turner, El Paso. Other officers of the association include: Dr. Francis J. L. Blasingame, Wharton, president-elect; Dr. Andrew S. Tomb, Victoria, vice-president; Dr. John M. Travis, Jacksonville, secretary; Dr. Thomas H. Thomson, Fort Worth, treasurer; and Mr. N. C. Forrester, executive secretary. The chronicle of the association has been recorded by Dr. Patrick I. Nixon of San Antonio in a 476 page volume "A History of the Texas Medical Association, 1853-1953," which was authorized by the board of trustees in observation of the centennial jubilee.

COUNCIL ON INDUSTRIAL HEALTH

Dr. William P. Shepard, New York, second vice-president, health and welfare division, Metropolitan Life Insurance Company, has been elected chairman of the American Medical Association's Council on Industrial Health. Dr. Shepard succeeds Dr. Anthony J. Lanza, New York, director of the Institute of Industrial Medicine, New York University-Bellevue Medical Center. Two new members of the council also have been elected: Dr. Lemuel C. McGee, Wilmington, Del., medical director, Hercules Powder Company, and Dr. Charles F. Shook, Toledo, Ohio, medical director, Owens-Illinois Glass Company. They succeed Dr. Lanza and Dr. Clarence D. Selby, Port Huron, Mich., whose terms have expired.

The presentation of two American Medical Association citations for distinguished service in the field of industrial health was made at the meeting. The awards went to Dr. Anthony J. Lanza and Dr. Clarence D. Selby, Port Huron, Mich., former medical consultant to the General Motors Corporation, Detroit. Announcement of the citations, the first in the field of industrial health, was made by Dr. George F. Lull, Chicago, Secretary and General Manager of the American Medical Association. Drs. Lanza and Selby have been leaders in the movement for better health conditions among workers.

STUDENTS' ANNUAL CONVENTION MAY 1-3 IN CHICAGO

The Student American Medical Association's fourth annual convention, May 1-3 at the Sherman Hotel, Chicago, will offer a program of panel discussions, speakers, and exhibits. Highlights include a scientific paper, "On Becoming a Physician," by Detroit psychiatrist Leo H. Bartemeier, M.D.; a roundtable discussion entitled, "Tell me, Dean," moderated by John F. Sheehan, M.D., dean of Stritch School of Medicine, Chicago, and a forum, "The Future of Internships." The house of delegates, official policy-making body of the association, will be in session May 1 and 3, with Sunday, May 2, to be devoted to the program proper. Members of SAMA and physicians are cordially invited.

MORE "MARCH OF MEDICINE" TV SHOWS

Of interest to physicians and patients afflicted with arthritis or rheumatism is the second in the spring, 1954, series of "March of Medicine" television programs. Sponsored by Smith, Kline and French Laboratories in cooperation with the American Medical Association, "A Status Report on Arthritis and Rheumatism" will be carried April 29 over the National Broadcasting Company's TV network. The third program in the series, on June 24, will originate from the A. M. A.'s annual meeting in San Francisco. Like last year's series, the new "March of Medicine" programs will be presented at 10 p. m. (EST); it will replace the "Martin Kane" show, which is usually seen at that hour.

AUDIO-DIGEST PROFITS GO TO MEDICAL SCHOOLS

The American Medical Education Foundation recently announced that a new source of funds now is available to medical schools through physician-support of the Audio-Digest Foundation. For a nominal weekly subscription fee, physicians receive from the Audio-Digest Foundation tape-recorded abstracts of current literature and lectures culled from current medical periodicals in all fields of medicine. This foundation, organized by the California Medical Association, will turn over its profits to the AMEF. This should boost the AMEF's 1954 campaign drive for funds from the medical profession to assist the country's 79 approved medical schools.

FEDERAL MEDICAL LEGISLATION

National Fund for Medical Education

Congressman Poff (R., Va.) in H. R. 7914, a companion bill to S. 1748 by the late Senator Taft, would give a federal character to the National Fund for Medical Education. The Poff measure differs from the Taft bill in only minor details, such as limiting the number of trustees to 17 and requiring that 4 of these be physicians. It specifies also that the contributions can be raised only from private sources. This measure was referred to the Committee on the Judiciary, which has already held a hearing thereon.

STATE MEDICAL LEGISLATION

Arizona

Bills Introduced.—H. 294, proposes regulations for the compulsory isolation and hospitalization of persons infected with tuberculosis. H. 295, proposes the creation of a division of tuberculosis control, the director of which shall be a physician licensed by the state of Arizona who has had not less than five years' experience in the control of tuberculosis. H. 307, proposes the creation of an Arizona bureau of narcotics enforcement to coordinate the activities of law enforcement officers and of state agencies in the enforcement of the narcotics act. S. 104, proposes regulations for the creation of hospital districts.

Bill Enacted.—S. 42, has become Chapter 6 of the Laws of 1954. It provides that any person who may otherwise validly make a will may, by will or other written, signed, and acknowledged instruments, dispose of the whole or any part of his body to a teaching institution, university, college, state department of health, facility designated or maintained by the anatomy board of Arizona, legally licensed hospital, any other agency or commission operating a tissue, eye, bone, cartilage, or blood bank, or any other bank of a similar kind designated for the purposes of medical science and the rehabilitation of the maimed.

Kentucky

Bills Introduced.—H. 401, proposes regulations for the effective control of the spread of communicable tuberculosis. H. 139, proposes regulations relating to the control of rabies. H. 409, proposes the creation of a department of the handicapped to exercise all functions of the state relating to the diagnosis, treatment, education, institutional care, vocational guidance, and placement and research for handicapped persons. The commissioner of this department would be required to be a qualified physician licensed to practice in the state with five years' experience in the field of public health administration.

The summary of federal legislation was prepared by the Washington Office of the American Medical Association and the summary of state legislation by the Bureau of Legal Medicine and Legislation.

Massachusetts

Bills Introduced.—H. 2479, proposes to authorize the construction of hospitals for use as homes or hospitals for aging persons who are not mentally ill. H. 2495, proposes that in any proceeding to establish paternity the trial court, on motion of the defendant, shall order the mother, her child, and the defendant to submit to one or more blood grouping tests, to be made by a duly qualified physician or other duly qualified persons designated by the court, to determine whether the defendant can be excluded as being the father of the child, and the results of such tests shall be admissible in evidence in cases where definite exclusion is established.

Mississippi

Bills Introduced.—H. 615, proposes to require licenses issued by the board of health before any person may engage in selling, distributing, or marketing instruments or devices designed for or represented as aiding, improving, or correcting defective hearing. H. 634, proposes regulations for the control of rabies. H. 656, proposes the creation of a cancer committee to serve with the state hospital commission, whose duty it shall be to decide in which cases operating room and/or blood transfusion fees shall be paid and the amount thereof. S. 1517, proposes to require both applicants for a marriage license to present a medical certificate indicating that the parties have submitted to a standard serologic test or tests for syphilis.

New York

Bills Introduced.—A.R. 120, proposes to direct the joint legislative committee to inquire into and make a thorough, complete, and careful study of the admission practices of the medical schools of the city and state of New York to determine if such admission practice results in discrimination against applicants by reason of race, creed, color, or national origin. A. 2555, proposes the creation of a temporary commission to study the needs of children and youth and to recommend a program to meet those needs. A. 2673 and S. 2690, propose the creation of a board of bioanalytical examiners and proposes that a person practices analytical technology who holds himself out as being able to perform or who performs or supervises others in performing any bacteriological, biochemical, microscopic, serologic, parasitological, and/or other tests by the practical application of one or more of the fundamental sciences by the use of specialized apparatus, equipment, and methods for the purpose of making scientific investigations, the results of which, when reported to a physician, osteopath, dentist, or podiatrist, may be used as an aid to ascertain the state of health. A. 2792, proposes the creation of a temporary commission to make a study and survey in reference to recommending legislation providing for the licensing of all those except medical doctors who prescribe or sell hearing aids. A. 2800, to amend the education law, proposes to define the word "physician" as including a practitioner of either osteopathy or naturopathy. A. 2832, to amend the social welfare law, proposes that no certificate of incorporation shall be filed that includes among its corporate purposes the operation of private proprietary hospitals, nursing homes, infirmaries, homes or institutions for convalescents, aged, or indigent persons, and lying-in homes operated for profit except with the written approval of the board and a justice of the supreme court. A. 3040 and S. 2452, propose the creation of a state board of massotherapists examiners and defines the practice of massage as a scientific system of applied activity of the muscular structures of the human body, by the means of stroking, kneading, tapping, and vibrating of such structures with the hands for the cardinal purpose of improving the circulation. It excludes the reduction of fractures or dislocations of the bones. A. 2856 and S. 2505, propose that every hospital supported in whole or in part by public funds or the solicitation of private subscriptions and to which patients are submitted on payment of a charge or fee or at which persons receive medical and/or surgical treatment on payment of a charge or fee may employ physicians and surgeons under a contract or salary arrangement for the medical diagnosis and/or treatment of patients only when such diagnosis and treatment is a public charge. In all other cases such medical diagnosis and/or treatment shall be rendered to patients in such hospital independently of other hospital charges and under contractual relationship between the patient and the physician. A. 2973, to amend the traffic law relating to the withdrawal of blood for the purpose of determining the alcoholic content therein, proposes that physicians shall not be liable for damages in any civil suit for withdrawing such blood except for gross negligence in the performance of such withdrawal. S. 2694, to amend the public health law, proposes circumstances under which a city health department may secure qualified full-time physicians for service during an emergency, even though such physicians are not citizens of the United States.

Rhode Island

Bill Introduced.—H. 748, proposes that no general release or settlement in writing signed by a person confined in a hospital shall be admissible in evidence in a trial or action to recover damages for personal injuries necessitating the hospitalization if the statement was obtained within fifteen days after the injuries except under certain specified circumstances.

Virginia

Bill Enacted.—S.J.R. 18, was adopted Feb. 10, 1954. It directs the Virginia Advisory Legislative Council to study the desirability and feasibility of providing specially designed geriatric facilities for the care of aged patients.

MEDICAL NEWS

CALIFORNIA

Medical Tour of Europe.—The California Medical Association has arranged its first annual grand medical tour of Europe, April 5-May 5. The itinerary provides for about one week in France and one in Italy, three days in England, three in Holland, two in Switzerland, and one in Belgium. Medical meetings are scheduled for Paris, Rome, Lucerne, and London. The total cost of the tour is \$1,788 (plus \$45.29 tax). Members' wives and children under 22 will receive the benefit of a family plan reduction. The party will leave San Francisco or Los Angeles by United Air Lines DC-6B Mainliner, April 5, arriving in New York the same evening and leaving the following day for Paris. On the return trip, arrival is scheduled for New York at noon, May 4, and departure for California the following day. Information may be obtained from the California Medical Association, 450 Sutter St., San Francisco 8.

ILLINOIS

Dr. Windle Goes to Maryland.—William F. Windle, Ph.D., scientific director of the Baxter Laboratories, Morton Grove, has been appointed chief of the Laboratory of Neuroanatomical Sciences of the National Institute of Neurological Diseases and Blindness, where he will continue his investigations into the problems of nerve regeneration. Dr. Windle previously served as chairman of the department of anatomy of the University of Pennsylvania, Philadelphia, and at the University of Washington, Seattle, and as director of the Institute of Neurology at Northwestern University, Chicago. He has held the Harvey lectureship, the War-Navy award, and the Sesquicentennial medal of the University of Louisville.

Chicago

Personal.—At the meeting of the Society of Illinois Bacteriologists, Feb. 27, Dr. Tibor Benedek, assistant clinical professor of dermatology and syphilology, Stritch School of Medicine of Loyola University, delivered a paper on the *Bacillus endoparasiticus* Benedek 1927. —Dr. Benjamin M. Gasul will present before the Memphis Heart Association "Advances in Pediatric Cardiology" March 22 and will hold a clinic the following morning.

Northwestern's New Medical Research Building.—According to J. Roscoe Miller, M.D., president of Northwestern University, construction of the seven-story Morton Medical Research Building was begun in February at 310 E. Superior St. on the Chicago campus. The new building will be financed by a 2 million dollar bequest left to the university by Mrs. Margaret Gray Morton, and it will be connected with a wing of the Ward building. A special feature will be movable metal wall partitions that can be set up at any 10-foot interval within the building, allowing laboratories to be converted at a moment's notice to almost any size desired. Fourteen specially designed chemical hoods for experiments with noxious fumes will be built. An electrical power supply of 576,000 watts will be conducted in a bus duct system unusual in a research building, and a continuous run of copper bars for conducting electricity will be constructed in all corridors of the building. Switches can be attached at any 1-foot interval along the bars to provide power at almost any point in the building.

KANSAS

Clendening Lectures.—Dr. Douglas Guthrie, lecturer in the history of medicine at the University of Edinburgh in Scotland, will be the Clendening memorial lecturer March 24-25. On Wednesday, 11 a. m., at the University of Kansas School of Medicine, Lawrence, his topic will be "Witchcraft and Witch Doctors." In

the evening Dr. Guthrie will speak in the Library of the History of Medicine at 8 p. m. The lecture at the University of Kansas School of Medicine, Kansas City, at 12 noon the following day will be "Lister and His Achievement." Physicians and students are invited.

MAINE

Clinics to Be Held.—Pediatric clinics are scheduled to be held at the Northern Maine Sanatorium, Presque Isle, March 24, 1:30 p. m., and at the Eastern Maine General Hospital in Bangor March 26, 1:30 p. m. A tumor clinic has been scheduled at the latter hospital March 25, 1:30-3 p. m., and a cardiac clinic, March 26, 9 a. m. to 12 noon.

Society News.—At a recent meeting of the Maine Society of Anesthesiologists the following officers were elected: Dr. George E. Sullivan, Bingham, president; Dr. Valentine J. Moore, Waterville, vice-president; and Dr. John R. Lincoln, Portland, secretary-treasurer. —The Maine Society of Radiologists recently elected the following officers: Dr. John Southworth, Togus, president; Dr. Clark F. Miller, Lewiston, vice-president; Dr. Jack Spencer, Portland, secretary-treasurer; and Dr. Forrest B. Aimes, Bangor, councilor to the American College of Radiology.

MARYLAND

Cancer Lecture.—Under the sponsorship of the house staff of Sinai Hospital, Baltimore, Dr. Sidney Farber, professor of pathology, Harvard Medical School, Boston, will deliver the Dr. Jack W. Kolson memorial lecture, "Approaches to the Chemotherapy of Cancer," March 25, 8:30 p. m. in Hurd Hall, Johns Hopkins Hospital, Baltimore. Physicians, medical students, and those in allied fields are invited.

MASSACHUSETTS

Dr. Rhoads to Lecture on Neoplastic Diseases.—The Alpha Theta chapter of the Phi Delta Epsilon fraternity at Tufts College Medical School, Boston, will hold the seventh annual lectureship March 22. The guest speaker will be Dr. Cornelius P. Rhoads, Sloan Kettering Institute, Memorial Center for Cancer and Allied Diseases, New York, who will discuss "Advances in the Treatment of Neoplastic Diseases."

Symposium on Poliomyelitis.—Dr. Charles A. Janeway, Boston, will serve as moderator for the following program of the Norfolk District Medical Society, March 23, 8:15 p. m. in the Jimmy Fund Building Auditorium, Children's Medical Center, 35 Binney St., Boston:

- Louis Weinstein, Boston, Diagnosis of Acute Poliomyelitis.
- R. Cannon Eley, Boston, Treatment of the Usual Case.
- Bertrand C. Kriete, Boston, Recognition and Management of Dangerous Complications of the Acute Disease.
- Thomas H. Weller, Boston, Poliomyelitis Viruses and Vaccines.
- Roy F. Feemster, Boston, Present Status of Methods of Prevention and Control.

Course on Measurement of Pulmonary Function.—A course in the measurement of pulmonary function in health and disease will be held for physicians in the New England area at Boston City Hospital, March 22-26 under the sponsorship of the American Trudeau Society, in cooperation with the Massachusetts Tuberculosis and Health League, Harvard Medical School, Boston University School of Medicine, and Tufts College Medical School. The course will present the fundamental concepts and methods of analysis of normal and abnormal physiology of the lungs in a manner that can be readily understood by physicians unfamiliar with this type of chest work. Information may be obtained from Dr. Edward J. Welch, chairman, ATS Regional Committee on Postgraduate Courses, 1101 Beacon St., Brookline 46.

Physicians are invited to send to this department items of news of general interest, for example, those relating to society activities, new hospitals, education and public health. Programs should be received at least three weeks before the date of meeting.

MINNESOTA

George E. Fahr Lecture.—The annual George E. Fahr lecture, "Some Pitfalls in the Care of Cardiacs," will be given March 23 in Owre Amphitheater on the University of Minnesota campus in Minneapolis by Dr. Samuel A. Levine, clinical professor, Harvard Medical School, Boston. Dr. Levine will also participate in the continuation course in cardiovascular diseases which will be held March 22 to 24 at the Center for Continuation Study.

Dr. Ulrich Honored.—The Hennepin County Tuberculosis Association, which on Dec. 2, 1953, observed the half-century mark in its "building of the wall" against tuberculosis, presented to Dr. Henry L. Ulrich, Minneapolis, a plaque in recognition of his many years of work toward the eradication of tuberculosis. Speakers at the golden jubilee of the association, which was founded a year before the creation of the National Tuberculosis Association and two years before the Minnesota state association, included Drs. S. Marx White, Walter J. Marcle, and Stewart C. Thomson, Minneapolis.

NEW JERSEY

Medicolegal Meeting.—The New Jersey Neuropsychiatric Association will hold an evening medicolegal meeting at the Academy of Medicine, Newark, March 24. The Briggs law and its relationship to psychiatric testimony will be discussed. Members of the medical and legal professions are invited.

Personal.—Dr. Samuel Cohen was recently appointed director of medicine at the Berthold S. Pollak Hospital for Chest Diseases, Jersey City. —Dr. Richard H. Roberts, Summit, has assumed the position, newly created by Ciba Pharmaceutical Products, of senior clinical research associate on the West Coast, where his address is 417 Market St., San Francisco.

NEW YORK

Cancer Program.—A cancer teaching day will be held March 25, 9 a. m. to 5 p. m., at Albany Medical College under the sponsorship of the college, the Medical Society of the County of Albany, Medical Society of the State of New York, and the New York State Department of Health. The program, conducted by members of the Jefferson Medical College of Philadelphia, will be presented in two parts. In the morning "Cancer of the Bronchus" will be discussed by Drs. John H. Gibbon Jr., Peter A. Herbut, Louis H. Clerf, and Theodore P. Eberhard, and in the afternoon "Treatment of Leukemia" will be presented by Drs. Franklin R. Miller, John S. Flint, and Theodore P. Eberhard.

Buffalo Clinical Day.—The Alumni Association of the University of Buffalo School of Medicine will conduct its annual Clinical Day, March 20, at the Hotel Statler, Buffalo. Physicians are invited to attend the sessions and join in the luncheon-get-together on the same payment basis as Alumni Association members. Dr. George M. Masotti, president of the alumni association, announces the following program:

- Problems in the Resuscitation of the Newborn Infant, Richard L. Day, New York.
- Surgical Treatment of Ulcerative Colitis—A Medical and Surgical Program, Garnet W. Ault, Washington, D. C.
- Portacaval Shunting for Portal Hypertension, with Special Reference to Cirrhosis of the Liver, Arthur H. Blakemore, New York.
- Early Diagnosis of Malignant and Pre-Malignant Lesions of the Colon and Rectum, Neil W. Swinton, Boston.
- Some Pitfalls in the Care of Cardiacs, Samuel A. Levine, Boston.
- Measures in the Prevention of Maternal Morbidity and Mortality, Robert A. Ross, Chapel Hill, N. C.

New York City

Society News.—The Association for the Aid of Crippled Children has moved to 345 E. 46th St. (OXford 7-3150). —At the meeting of the Society for the Study of Blood, March 23, 8:30 p. m., at the New York Academy of Medicine, "Platelet Transfusions in the Control of Thrombocytopenic Bleeding" will be discussed by Dr. Allen H. Minor, research associate, Lennox Hill Hospital, and "Immunologic Mechanisms in Idiopathic Thrombocytopenic Purpura" by Dr. William J. Harrington, senior assistant surgeon, U. S. Public Health Service, National Institute of Arthritis and Metabolic Diseases, Bethesda, Md.

Lectures on Anesthesiology.—Modern scientific method and modern statistics with special application to anesthesiology will be presented by Dr. Philip H. Sechzer, director of anesthesiology, Fordham and Seton hospitals, and consultant, U. S. Public Health Service, Staten Island, at 1:30 p. m. March 25, April 22, and May 20 in Ward 9, auditorium, Fordham Hospital. The topics to be presented are: logic and scientific method, the meaning of statistics, how to evaluate evidence, bias and variations, enumeration data, confidence limits, chi square test, mensuration data, T test, correlation and regression, simple experiments, and factorial design. The profession is invited.

Biology Seminars.—New York University is presenting a series of graduate biology seminars open to all interested persons, at 5 p. m. on Friday evenings in NYU's Main Building, Washington Square Center. On March 19, Dr. Albert Tannenbaum, director, department of cancer research, Medical Research Institute of Michael Reese Hospital, Chicago, discussed "Nutrition in Relation to the Cancer Process," and, on March 26, George Wald, Ph.D., professor of biology, Harvard University, Cambridge, Mass., will present "The Molecular Basis of Vision." The following programs complete the schedule: April 2, John Tyler Bonner, Ph.D., associate professor of biology, Princeton University, Princeton, N. J., "Recent Studies on the Development of the Slime Mold, Dictyostelium Discoideum"; April 23, Horace W. Stunkard, Ph.D., professor of biology at New York University, "Parasitism as a Biological Phenomenon"; and April 30, James H. McGregor, Ph.D., professor emeritus of zoology at Columbia University, "Comparison of Apes and Man."

OREGON

Harmon Lectures.—The Harmon lecture series, presented annually by the Library Association of Portland, will be co-sponsored this year by the University of Oregon Medical School, Portland, making possible medical talks designed for laymen. The lectures, presided over by Dr. Daniel H. Labby, associate professor of medicine, will include: Dr. Howard P. Lewis, professor and head of the department of medicine, "Facing the Medical Problems of Aging," March 24; Dr. S. Gorham Babson, assistant clinical professor of pediatrics, "The Signs of Emotional Strain in Our Children," March 29; Dr. Roy L. Swank, professor of neurology, "Approaches to a Mysterious Disease—Multiple Sclerosis," April 8; and Dr. Joseph F. Paquet, clinical associate in medicine, "What's New in Poliomyelitis," April 21.

PENNSYLVANIA

Memorial to Dr. Laplace.—The Aid Association of the Philadelphia County Medical Society announces the establishment of the Dr. Louis B. Laplace Memorial Fund as a tribute to Dr. Laplace who died a few days before the termination of his service as a director of the association. Individual or group contributions may be sent to the Aid Association, Philadelphia County Medical Society, 21st and Spruce streets, Philadelphia 3, earmarked for the "Dr. Louis B. Laplace Memorial Fund."

Philadelphia

Alpha Omega Alpha Lectureship.—The Temple University chapter of Alpha Omega Alpha will present its annual lectureship March 22, 4 p. m., in the auditorium of Temple University School of Medicine, 3400 N. Broad St. Dr. Charles A. Hufnagel, professor of surgical research, Georgetown University School of Medicine, Washington, D. C., will discuss "The Reconstructive Concept in the Treatment of Diseases of Major Arteries."

VERMONT

Surgeons Meet in Montpelier.—The spring meeting of the section on surgery of the Vermont State Medical Society will be held March 25 at the Pavilion in Montpelier. Dr. Robert R. Linton, assistant professor of clinical surgery, Harvard Medical School, Boston, will discuss "New Parts for Old in the Surgical Treatment of Diseases of the Major Arteries" before the social hour which precedes the 6:30 banquet. He will also show his film "Treatment of Venous Thrombosis of the Lower Extremity." Dinner reservations are essential. Dr. Benjamin F. Clark, St. Johnsbury, is chairman of the program committee.

The Lutheran Minor Hospital for the Treatment of Chronic Illness is the first new hospital in the state to deal specifically with this problem. Located at Puyallup, adjacent to the Lutheran Home for the Aged and closely affiliated with the local general hospital, it has 76 beds and facilities for physical and occupa-

NEW HOSPITALS IN THE STATE OF WASHINGTON

Reading from top and left to right are Skyline Hospital, White Salmon; St. Helen Hospital, Chehalis; Olympic Memorial Hospital, Port Angeles; Adams County Memorial Hospital, Ritzville; St. Martin's Hospital, Tonasket; Memorial Hospital, Sedro Woolley; St. Joseph Hospital, Aberdeen; and Yakima Valley Memorial Hospital, Yakima.

tional therapy, minor surgery, and laboratory and x-ray. The Lutheran Welfare Society undertook to construct this hospital with funds raised through public subscription and mortgage loan, but, as these were insufficient, a Hill-Burton grant was approved for the purchase of equipment.

University, state, and Hill-Burton funds made possible construction of the first unit of the 300 bed University of Washington Teaching Hospital in Seattle, a clinic research unit adjoining the Health Sciences Building on the university campus. Physicians throughout the state will be able to refer patients to the outpatient clinic in this unit to receive the benefit of highly specialized studies and examinations. This structure contains a small referral diagnostic clinic for outpatients and 24 beds for inpatients, which beds will be limited to medical research purposes.

The 20 bed Adams County Memorial Hospital at Ritzville serves the large and prosperous but sparsely populated wheat farming area of eastern Washington. Constructed by the Adams County Public District no. 1 at a total cost of \$336,000, it replaces the former inadequate Ritzville General Hospital, which was housed in quarters converted from a doctors clinic and home. This new hospital has made it possible for surgeons from Spokane to serve the people of this rural area.

By the end of 1952 the construction of new facilities had added more than 1,000 beds in general hospitals, at which time the state had a total of 8,313 general hospital beds. The previously mentioned brochure states that at that time a leveling off in the need for general hospital beds appeared to have taken place partly as a result of a trend toward a shorter length of patients' stay in the hospital and "partly due to the new 'wonder' drugs that have made some use of hospitals unnecessary."

GENERAL

Eastern Surgeons Meet in Boston.—The Eastern Surgical Society will meet in Boston, March 26-27. From 8:30 a. m. until noon, operative and dry clinics will be held at the Massachusetts General Hospital on both days. On Friday after luncheon at the Massachusetts General Hospital, a program will be presented from 2 to 4 p. m. at the Peter Bent Brigham Hospital by the staff.

Areas in Need of Physicians.—Information concerning openings for general practitioners in Pennsylvania, West Virginia, and Ohio has been compiled by the area medical office of the United Mine Workers of America Welfare and Retirement Fund, Empire Building, 507 Liberty Ave., Pittsburgh. Information concerning openings in other states has been compiled by the national office and other area medical offices of the fund.

Accidental Deaths in 1953.—The National Safety Council reports that during 1953, accidents in the United States killed 95,000 persons (more than three times as great as the toll of American dead during the entire Korean war), injured 9,600,000 and cost 9 billion dollars. The 1953 accident death toll was, however, 1,000 below that of the year before, and the 1953 all-accident death rate (60 per 100,000 population) was the lowest on record.

Allergists Meet in Atlanta.—The annual meeting of the South-eastern Allergy Association will be held at the Hotel Dinkler Plaza in Atlanta, March 25-27, under the presidency of Dr. W. Lindsay Miller, Gadsden, Ala. The program will include addresses by Dr. Homer E. Prince, Houston, Texas, president-elect of the American Academy of Allergy; Dr. John M. Sheldon, Ann Arbor, Mich., president, American Academy of Allergy; Dr. Ethan Allan Brown, Boston, editor, *Annals of Allergy*; Dr. Oscar Swineford, Charlottesville, Va., past president of the American Academy of Allergy; and Albert S. Richardson, Ph.D., associate director of the chemical division of Proctor and Gamble, Cincinnati.

Symposium on Drug Resistance.—A symposium on the origins of resistance to drugs will be presented under the sponsorship of the Office of Naval Research and the University of Pennsylvania March 25-27 in Washington, D. C. The symposium will consist of six successive sessions, each devoted to one of the

following topics: (1) origins of microbial drug resistance; (2) tolerance and addiction to drugs, and alcoholism; (3) resistance to insecticides, herbicides; (4) factors in resistance to infectious agents; (5) biochemical mechanism of carcinogenesis and the nature of tumor immunity; and (6) integration of the questions of resistance from the genetic, physiological, and chemical points of view.

Scholarships in Public Health.—The Harvard School of Public Health is initiating postgraduate scholarships in amounts ranging up to \$5,000 to qualified candidates desiring to study at the school during the academic year 1954-1955. These scholarships are available to (1) physicians, dentists, and veterinarians interested in preventive medicine and seeking training in one or more public health specialties leading to a master of public health or a doctor of public health degree; (2) industrial physicians seeking training in industrial medicine leading to a master of industrial health degree; (3) public health nurses with a college degree and satisfactory field experience who wish additional public health training leading to a master of public health degree; (4) public health engineers seeking additional training and research experience in one or more public health specialties leading to either a master of science in hygiene or a doctor of science in hygiene degree; and (5) college graduates with academic experience in the natural sciences who desire training and research experience in one of the sciences related to public health and leading to either a master of science in hygiene or a doctor of science in hygiene degree. Applications must be filed by April 30. Winners will be announced June 1. Information may be obtained from the Secretary, Harvard School of Public Health, 55 Shattuck St., Boston 15.

Psittacosis Reported.—According to the U. S. Public Health Service, psittacosis virus was recently recovered from two parrots sent to a game farm in Virginia. X-ray examination of the attendant who cared for the birds showed evidence of pneumonitis about one week after discharge from a hospital where he was treated for pneumonia. A specimen of blood from the attendant was positive 1:8 with *Lygranum* antigen.—Psittacosis infection was reported in three parakeets in Connecticut, one of which had been imported from Florida and two from New York City from a source which had previously been incriminated. Reports have been made of four suspected cases in human beings and of two actual cases of psittacosis, in both of which the blood showed a positive complement fixation test in a titer of 1:128.—Pursuant to information received from the Tennessee health commissioner, indicating that human cases of psittacosis in that state had been traced to contact with parakeets purchased in North Carolina, an investigation by the North Carolina State Board of Health disclosed six cases of atypical pneumonia in the family of the owner of the aviary from which the parakeets had been purchased. It was reported that a large number of persons raise psittacine birds in this area and that many cases of atypical pneumonia have occurred. Blood samples and several birds have been sent to the virus laboratory of the Communicable Disease Center.

General Practitioners Meet in Cleveland.—The American Academy of General Practice will hold its annual scientific assembly March 22-25 at the Public Auditorium in Cleveland. At 1:30 p. m. Monday Dr. Edward J. McCormick, Toledo, Ohio, President of the American Medical Association, will deliver the address "The Physician as a Citizen." Presentations by Dr. Roscoe L. Pullen, Columbia, Mo. (Why Train for General Practice?) and Dr. Joseph Hughes, Philadelphia (The Family Doctor and Our Youth) will follow. At 4 p. m. Dr. Howard A. Rusk, New York, will conduct a clinic on rehabilitation. The Tuesday session will open at 9 a. m. with presentation of "Significance of Thyroid Enlargement" by Dr. George Crile Jr., Cleveland, which will be followed by "Emergency Room Surgery" by Dr. Donald M. Glover, Cleveland, "Allergic Dermatitis" by Dr. George H. Curtis, Cleveland, and "Commonly Missed Diagnoses of Skin Diseases" by Dr. Clarence S. Livingood, Detroit. The afternoon session will be devoted to a symposium on peptic ulcer (Dr. C. Stuart Welch, Albany, N. Y., moderator) and a

symposium on tuberculosis (Dr. Sol Katz, Washington, D. C., moderator). Wednesday at 11:30 a. m. Dr. Richard W. TeLinde, Baltimore, will discuss "Unnecessary Surgery in Ob-Gyn." His presentation will be preceded by "Medical Complications in Obstetrics" by Dr. Robert M. Myers, Kansas City, Mo., "Management of Vaginal Bleeding" by Dr. Robert L. Faulkner, Cleveland, and "The Routine Multip" by Dr. Allan C. Barnes, Columbus, Ohio. The Wednesday afternoon session will open with a symposium "Headache, Dizziness and Syncope," which will be moderated by Dr. Theodore J. von Storch, New York. At 4 p. m. Sir Alexander Fleming will have as his topic "Beginning of Antibiotic Therapy." The afternoon session will conclude with a symposium on antibiotics in infectious diseases, for which Dr. Paul A. Bunn, Syracuse, N. Y., will serve as moderator. On Thursday rheumatic arthritis will be discussed by Dr. Thomas F. Frawley, Albany, N. Y., other collagen diseases by Dr. Robert Strecher, management of the anemias by Dr. William S. Middleton, Madison, Wis., and recent advances in therapeutics by John C. Krantz Jr., Ph.D., Baltimore. The president's reception will be held in the ballroom of the Hotel Cleveland Wednesday evening.

MEETINGS

AMERICAN MEDICAL ASSOCIATION: Dr. George F. Lull, 535 North Dearborn St., Chicago 10, Secretary.
 1954 Annual Meeting, San Francisco, June 21-25.
 1954 Clinical Meeting, Miami, Florida, Nov. 29-Dec. 2.
 1955 Annual Meeting, Atlantic City, N. J., June 6-10.
 1955 Clinical Meeting, Boston, Nov. 29-Dec. 2.
 1956 Annual Meeting, Chicago, June 11-15.

AERO MEDICAL ASSOCIATION, Hotel Statler, Washington, D. C., March 29-31. Dr. Thomas H. Sutherland, P. O. Box 26, Marion, Ohio, Secretary.

ALABAMA, MEDICAL ASSOCIATION OF THE STATE OF, Mobile, April 15-17. Dr. Douglas L. Cannon, 537 Dexter Ave., Montgomery, Secretary.

AMERICAN ACADEMY OF GENERAL PRACTICE, Cleveland, March 22-25. Mr. Mac F. Cahal, 406 West 34th St., Kansas City 2, Mo., Executive Secretary.

AMERICAN ACADEMY OF NEUROLOGY, Shoreham Hotel, Washington, D. C., April 29-May 1. Dr. Alexander T. Ross, 1040 West Michigan St., Indianapolis 7, Secretary.

AMERICAN ASSOCIATION OF ANATOMISTS, Hotel Galvez, Galveston, Texas, April 7-9. Dr. Normand L. Hoerr, 2109 Adelbert Road, Cleveland 6, Secretary.

AMERICAN ASSOCIATION FOR CLEFT PALATE REHABILITATION, Webster Hall Hotel, Pittsburgh, May 14-15. Dr. Jack Matthews, 1617 Cathedral of Learning, University of Pittsburgh, Pittsburgh 13, Secretary.

AMERICAN ASSOCIATION OF THE HISTORY OF MEDICINE, Hotel Taft, New Haven, Conn., May 6-8. Dr. Samuel X. Radbill, 7043 Elmwood Ave., Philadelphia 42, Secretary.

AMERICAN ASSOCIATION OF IMMUNOLOGISTS, Ambassador Hotel, Atlantic City, N. J., April 11-15. Dr. John Y. Sugg, 1300 York Ave., New York, Secretary.

SOUTH DAKOTA: Examination. June 11-12. Sec., Dr. Gregg M. Evans, 310 E. 15th St., Yankton.

TEXAS: Examination. April 1954. Location determined by number of applicants from different sections of the state. Sec., Brother Raphael Wilson, C.S.C., 407 Perry-Brooke Bldg., Austin.

WISCONSIN: Examination. Madison, April 3 and June 5. Final date for filing application is March 26 and May 28. Sec., Dr. W. H. Barber, 621 Ransom St., Ripon.

*Basic Science Certificate required.

DEATHS

Herrick, James Bryan ☉ Chicago, a recipient of the Distinguished Service Medal of the American Medical Association, died in the Presbyterian Hospital March 7, aged 92, of carcinoma of the stomach and peritonitis. Dr. Herrick was born in Oak Park, Ill., Aug. 11, 1861. He attended Oak Park High School and the Rock River Seminary at Mount Morris, Ill., and was graduated from the University of Michigan, Ann Arbor, in 1882. For a time he taught in the Central High School, Peoria, Ill., acquiring there a love of good literature and a facility for expressing himself in the English language. Through his association with Moses Coit Tyler he developed a great interest in Chaucer. Dr. Herrick then took up the study of medicine, receiving the degree of doctor of medicine from Rush Medical College in 1888. On completing his internship at Cook County Hospital, he joined the staff of his alma mater, serving as instructor in medicine from 1890 to 1894, adjunct professor from 1894 to 1900, professor from 1900 to 1927 and then became emeritus. In 1930 a fellowship was named in his honor at Rush Medical College by Dr. Frank Billings. He had been a member of the staff of Presbyterian Hospital since 1890, serving as president of the medical board from 1908 to 1913 and as vice-president from 1903 to 1907. He was attending physician to the Presbyterian Hospital from 1890 to 1924 when he was made consultant. A bas-relief portrait of him was presented to the hospital Nov. 6, 1943, as a feature of special anniversary exercises. The first electrocardiograph used in Chicago was in his office, and he was instrumental in having installed in the Presbyterian Hospital the first electrocardiograph used in any hospital in the city. He was identified with the Central Free Dispensary for many years and for a time was chairman of the medical advisory committee of Sunset Camp, a convalescent colony sponsored by the Chicago Heart Association. Herrick House, a camp for rheumatic heart victims in Fox River Valley, was named for him. A member of many scientific societies and a specialist certified by the American Board of Internal Medicine, Dr. Herrick served as president of the Society of Medical History of Chicago, American Association for the History of Medicine, Association of American Physicians, American Heart Association, which in 1951 presented him with a gold heart award, and of the Congress of American Physicians and Surgeons. In 1939, after concluding a year as vice-president of the American College of Physicians, the college conferred on him the title "master" for the first time in 11 years that the honor had been accorded. He was a founder of the Institute of Medicine of Chicago and active on its board of governors since 1915, holding the presidency in 1925. In October, 1949, several hundred fellows of the institute and prominent guests paid tribute to Dr. and Mrs. Herrick at a reception to mark the publication of Dr. Herrick's autobiography "Memories of Eighty Years." He was a member of the board of trustees of the Lewis Institute and the McCormick Memorial Institute, a past president of the Chicago Pathological Society and the Chicago Literary Club, and founder and first president of the Chicago Heart Association. He was founder and first president of the Chicago Society of Internal Medicine, and a member of the Central Society for Research. In 1935 a paper was prepared by Dr. William H. Holmes for the Central Interurban Clinical Club of which Dr. Herrick was an honorary member, reviewing his distinguished career as a student, teacher, and scientist. Notable awards were presented to Dr. Herrick, including honorary memberships and degrees from institutions and societies. In 1930 he received the Kober medal of the Association of American Physicians for research in scientific medicine, and in 1933 the New York Academy of Medicine elected him to honorary fellowship. He also received the "Gold Headed Cane" from the University of California Medical School in San Francisco for his accomplishments in the practice of medicine, in teaching, and in investigation. He gave such prominent lectures as the Fenger, George W. Gay, Harvey, and Abner Wellborn Calhoun lectures. In 1939, the American Medical Association, of which he was an

Associate Fellow and which he served as a member of the Judicial Council from 1928 to 1934, presented its Distinguished Service Medal to Dr. Herrick for his work on coronary thrombosis. A renowned internist, his articles on this subject are said to have done more to force clinical recognition of the conditions and to stimulate clinical and experimental study than all other writings on the subject. Probably most significant was the contribution "Clinical Features of Sudden Obstruction of the Coronary Arteries," published in *THE JOURNAL*, Dec. 7, 1912. He first described sickle cell anemia as a clinical entity in 1910. He was the author of "Handbook of Medical Diagnosis" and "A Short History of Cardiology." In 1907 he received the honorary degree of master of arts from the University of Michigan, which in 1932 awarded him the honorary degree of doctor of laws. In January, 1939, at the 194th convocation of the University of Chicago, the honorary doctorate of science was conferred on him and in June, 1940, the honorary degree of doctor of science was awarded to him by Northwestern University.

Burrier, Walter Painter ☉ Brookline, Mass.; born in Biddeford, Maine, April 12, 1882; Tufts College Medical School, Boston, 1908, specialist certified by the American Board of Psychiatry and Neurology; commissioned a surgeon in the U. S. Public Health Service from 1921 to 1924 when he joined the U. S. Veterans Bureau; lieutenant colonel in the Army of the United States from 1944 to 1946; formerly clinical director and executive officer at the Bronx Hospital in New York, where he was chief of the outpatient department; clinical director and executive officer, West Roxbury (Mass.) Hospital from 1924 to 1928; clinical director, Bedford (Mass.) Hospital from 1928 to 1934; chief of the neuropsychiatric division, Diagnostic Center, Washington, D. C., 1934-1935; clinical director at Veterans Administration Hospital, Northampton, Mass., from 1935 to 1937; clinical director from 1937 to 1945 and manager from 1945 to 1947 at the Veterans Administration Hospital in Bedford, Mass.; member of the Association of Military Surgeons of the United States, New England Society of Psychiatry, and the American Psychiatric Association; died in the Veterans Administration Hospital in West Roxbury, Jan. 28, aged 71, of carcinoma of the prostate.

Meyers, Milton Kayton ☉ Philadelphia; born in Philadelphia, Jan. 3, 1882; University of Pennsylvania Department of Medicine, Philadelphia, 1902; specialist certified by the American Board of Psychiatry and Neurology; instructor in child psychiatry at Jefferson Medical College; member of the Philadelphia Neurological Society, Pathological Society of Philadelphia, Northern Medical Society of Philadelphia, Anthropological Society, and Philadelphia Psychiatric Society; attending psychiatrist, Philadelphia Psychiatric Hospital; consulting neurologist, Jewish Hospital; neurologist, Northern Liberties Hospital; neuropsychiatrist, American Oncologic Hospital, assistant neurologist, Philadelphia General Hospital; translator and editor of Falta's "Endocrine Diseases, Including Their Treatment"; editor of "Lang's German-English Medical Dictionary"; contributor of the chapter on nervous diseases in Loewenberg's "Diagnostic Methods and Interpretations in Internal Medicine"; died Jan. 25, aged 72, of a heart attack.

Guequierre, Jacques Pierre ☉ Bryn Mawr, Pa.; born in Milwaukee Nov. 6, 1891; Marquette University School of Medicine, Milwaukee, 1924; specialist certified by the American Board of Dermatology and Syphilology; member of the American Academy of Dermatology and Syphilology; associate professor of dermatology and syphilology at Temple University School of Medicine and the Medico-Chirurgical College, Graduate School of Medicine, University of Pennsylvania, Philadelphia; member and past president of the Philadelphia Dermatological Society; corresponding member of the Cuban Dermatological Society and the Cuban Cancer Society; chief of clinic, department of dermatology and syphilology at Temple University Hospital; chief of clinic in the department of physical therapy at Graduate

Hospital; consultant of dermatology at the Philadelphia State Hospital; affiliated with Bryn Mawr Hospital, where he died Jan. 15, aged 62, of coronary thrombosis and pneumonia.

Blydenburgh, George Theron ☉ Delaware, Ohio; born in Brooklyn April 16, 1891; Cornell University Medical College, New York, 1918; assistant surgeon in the U. S. Naval Reserves at the Brooklyn Naval Hospital, 1918-1919; resident physician, Red Cross Hospital, New York, 1919-1920; member of the American Public Health Association; formerly secretary-treasurer of the American Student Health Association; from 1945 to 1952 on the board of directors of the Ohio Tuberculosis and Health Association; at one time a medical missionary, serving as superintendent of the Susan Toy Ensign Memorial Hospital in Nanchang, China from 1920 to 1931; assistant physician, New York State Department of Mental Hygiene, 1932-1933; Ohio Wesleyan University physician and director of student health service since 1933; died Jan. 22, aged 62, of congestive heart failure.

Kirkpatrick, William David ☉ Bellingham, Wash.; born in Chelsea, Mass., March 10, 1872; University of Minnesota College of Homeopathic Medicine and Surgery, Minneapolis, 1895; member of the Pacific Coast Surgical Association, of which he was one of the founders; fellow of the American College of Surgeons; past president of the Washington State Medical Association; medical officer both for the American Red Cross and the U. S. Army during World War I; cited by Queen Marie of Roumania for meritorious services; for many years trustee for the Western Washington College of Education; affiliated with St. Luke's Hospital and St. Joseph's Hospital, where he died Jan. 13, aged 81, of coronary occlusion.

Arkebauer, Charles A. ☉ Van Buren, Ark.; Missouri Medical College, St. Louis, 1899; formerly on the faculty of the University of Arkansas School of Medicine in Little Rock; member of the American Psychiatric Association; for many years affiliated with the State Hospital for Nervous Diseases in Little Rock; died in the Crawford County Hospital Oct. 22, aged 86.

Artis, G. Hubert, Los Angeles; Rush Medical College, Chicago, 1927; at one time practiced in Cedar Rapids, Iowa, where he was on the staffs of Mercy and St. Luke's Methodist hospitals; retired as medical examiner for the Baltimore and Ohio Railway in Cumberland, Md.; died in Centinela Valley Hospital in Inglewood, Calif., Dec. 12, aged 63, of cerebral hemorrhage.

Ayers, Thomas Wilburn, Atlanta, Ga.; College of Physicians and Surgeons, Baltimore, 1886; for many years a medical missionary in China; died Jan. 5, aged 95, of arteriosclerotic heart disease.

Barnard, Frank Steele, Los Angeles; Hahnemann Medical College and Hospital of Philadelphia, 1894; died Jan. 16, aged 94, of bronchopneumonia and arteriosclerosis.

Beers, Merritt Isaac ☉ Middletown, N. Y.; New York Homeopathic Medical College and Hospital, New York, 1901; an Associate Fellow of the American Medical Association; on the staff of the Elizabeth A. Horton Memorial Hospital; died Dec. 11, aged 76, of arteriosclerotic heart disease.

Bender, Max, Union City, N. J.; Jefferson Medical College of Philadelphia, 1915; served on the staffs of the Christ Hospital in Jersey City and the North Hudson Hospital in Weehawken; died Jan. 11, aged 66, of coronary thrombosis.

Bickel, James T. ☉ Lamar, Mo.; University Medical College of Kansas City, Mo., 1901; died Dec. 7, aged 81, of arteriosclerotic heart disease.

Biggers, John Alvin, Manhattan Beach, Calif.; University of Louisville (Ky.) Medical Department, 1907; veteran of the Spanish-American War; served on the staffs of the Los Angeles County General and Hollywood Presbyterian hospitals; died Jan. 7, aged 78, of lymphosarcoma.

Booth, William Telford ☉ Coronado, Calif.; Emory University School of Medicine, 1930; resigned from the regular Navy Jan. 4, 1938; killed in an airplane crash Jan. 23, aged 48.

Bright, John Fulmer, Richmond, Va.; Medical College of Virginia, Richmond, 1898; emeritus professor of anatomy at his alma mater; served during World War I; mayor of Richmond from 1924 to 1940; died in the Johnston-Willis Hospital Dec. 29, aged 76, of aortic stenosis.

Brooks, Isaac William, Torrington, Wyo.; College of Physicians and Surgeons, Dallas, Texas, 1905; died Jan. 20, aged 80, of cerebral hemorrhage.

Burns, William Milton ☉ North Little Rock, Ark.; University of Arkansas School of Medicine, Little Rock, 1914; for many years member of the school board; served as mayor; died Dec. 29, aged 75, of acute coronary thrombosis.

Bursheim, Peder Joseph ☉ Des Moines, Iowa; Keokuk (Iowa) Medical College, College of Physicians and Surgeons, 1905; died in the Iowa Lutheran Hospital Jan. 17, aged 70, of carcinoma of the colon.

Butt, Arthur Parker Jr. ☉ Elkins, W. Va.; University of Virginia Department of Medicine, Charlottesville, 1929; chief surgeon at Davis Memorial Hospital; died in Orlando, Fla., Dec. 16, aged 51, of coronary thrombosis.

Cafferky, Allan Bryan, Clarkston, Wash.; College of Medical Evangelists, Loma Linda and Los Angeles, 1945; served as a medical missionary; died in White Memorial Hospital in Los Angeles, Dec. 31, aged 33, of adenocarcinoma of the ascending colon.

Cardenas, Valentin Oriol ☉ Orlando, Fla.; Universidad de la Habana Facultad de Medicina y Farmacia, Cuba, 1927; member of the Illinois State Medical Society; formerly practiced in Chicago, where he was affiliated with the Columbus Hospital; affiliated with the Orange Memorial Hospital; served during World War II; died Jan. 31, aged 50, in a plane crash.

Coffey, George W., Concordia, Kan.; Kansas City (Mo.) Medical College, 1893; died Jan. 19, aged 87, as the result of a fall.

Cooper, Benjamin F. ☉ Detroit; Detroit College of Medicine, 1930; served during World War II; fellow of the American College of Surgeons; affiliated with Holy Cross Hospital and the East Side General Hospital; died in the Saratoga General Hospital Jan. 19, aged 47, of coronary occlusion.

Cozzolino, James Anthony, Hamden, Conn.; Jefferson Medical College of Philadelphia, 1920; on the staff of St. Raphael's Hospital in New Haven; died Jan. 12, aged 59, of myocardial infarction.

Danciger, Jacob Adolph ☉ Memphis, Tenn.; University of Tennessee College of Medicine, Memphis, 1937; assistant professor of pediatrics at his alma mater; specialist certified by the American Board of Pediatrics; member of the American Pediatric Society; past president of the Memphis Pediatrics Society; served during World War II; died in John Gaston Hospital Nov. 24, aged 39, of chronic glomerulonephritis.

Day, George Huff ☉ New Albany, Ind.; University of Louisville (Ky.) Medical Department, 1913; served in France during World War I; on the staff of St. Edward's Hospital; died Jan. 20, aged 63.

DeCanio, John ☉ Talihina, Okla.; Marquette University School of Medicine, Milwaukee, 1940; member of the Medical Association of Montana; associated with the Indian Service; served during World War II; formerly head physician at the Claremore Indian Hospital in Claremore; medical officer in charge of Talihina Medical Center, U. S. Indian Hospital; died Dec. 3, aged 43, of multiple myeloma.

Dever, Neal, McAdoo, Pa.; Temple University School of Medicine, Philadelphia, 1911; also a lawyer; medical inspector for the McAdoo Borough School District for many years; died Dec. 13, aged 81, of senility.

Dezell, Earl R., Glendale, Calif.; Minneapolis College of Physicians and Surgeons, medical department of Hamline University, 1908; died Dec. 30, aged 70, of coronary occlusion and arteriosclerosis.

Dillman, Theodore Albert, Ann Arbor, Mich.; University of Michigan Department of Medicine and Surgery, Ann Arbor, 1908; died in Detroit Jan. 6, aged 77, of arteriosclerosis.

Frey, Albert ☉ Buffalo; University of Buffalo School of Medicine, 1902; an Associate Fellow of the American Medical Association; affiliated with Deaconess Hospital; died Jan. 8, aged 74.

Gadol, William Norman ☉ Bethesda, Md.; Syracuse University College of Medicine, 1948; formerly assistant surgeon in the U. S. Public Health Service Reserve; died Jan. 17, aged 35, of coronary occlusion.

Hayward, Herbert ☉ Hamilton, Mont.; Milwaukee Medical College, 1908; fellow of the American College of Surgeons; served during World War I; chief surgeon, Marcus Daly Memorial Hospital, until his retirement two years ago; special consultant at the Rocky Mountain Laboratory; died suddenly Jan. 4, aged 71, of coronary thrombosis.

Hebble, Robert C., Springfield, Ohio; Starling Medical College, Columbus, 1895; past president of the Clark County Medical Society; on the courtesy staffs of the City Hospital and Mercy Hospital, where he died Dec. 5, aged 79, of coronary thrombosis.

Hochfeld, Herbert David ☉ Seattle; Universität Bern Medizinische Fakultät, Switzerland, 1935; on the staff of the Virginia Mason Hospital, where he died Dec. 24, aged 45, of a postoperative infection.

Hoeffel, Adelaide Doolittle ☉ Chicago; the Hahnemann Medical College and Hospital, Chicago, 1903; formerly on the faculty of her alma mater; on the courtesy staff of the Chicago Memorial Hospital, where she died Jan. 20, aged 86, of ruptured diverticulitis of the sigmoid colon, empyema of the gallbladder, and arteriosclerosis.

Hollingworth, Carl J., Portland, Ore.; University of Oregon Medical School, Portland, 1926; assistant clinical professor of medicine at his alma mater; a member of the board of directors of the Willamette University in Salem; formerly associated with the U. S. Public Health Service; died Jan. 14, aged 64, of rheumatic heart disease, coronary arteriosclerosis, and nephrosclerosis.

Horwitz, Sander ☉ Peoria, Ill.; Missouri Medical College, St. Louis, 1895; an Associate Fellow of the American Medical Association; member of the American Public Health Association; formerly district health officer for the state board of health, and health commissioner of Peoria; died in Chicago Jan. 17, aged 86, of coronary thrombosis.

Humphrey, Lester Hayden ☉ Silver Springs, N. Y.; Albany (N. Y.) Medical College, 1900; served as health officer for Gainesville; for many years county coroner; member of the Wyoming County Welfare Department; on the staff of the Wyoming County Community Hospital in Warsaw, where he died Nov. 14, aged 82, of cerebral hemorrhage.

Inge, Francis Marion ☉ Mobile, Ala.; Maryland Medical College, Baltimore, 1910; served during World War I; died in the Methodist Hospital, Houston, Texas, Jan. 13, aged 69, of abdominal aneurysm.

Lewin, Adolph Leo ☉ Pittsburgh; Western Pennsylvania Medical College, Pittsburgh, 1892; Friedrich-Wilhelms-Universität Medizinische Fakultät, Berlin, Germany, 1895; for many years member of the school board; affiliated with Western Pennsylvania, St. Francis, and Montefiore hospitals; died Dec. 31, aged 82, of coronary occlusion.

Lougee, William Wheeler ☉ Malden, Mass.; New York University Medical College, New York, 1898; past president of the Malden Medical Society; for many years medical inspector in Malden schools; served on the staff of Malden Hospital; trustee of the Malden Savings Bank; died Jan. 10, aged 86, of a heart attack.

McAnally, William Jefferson ☉ High Point, N. C.; Baltimore Medical College, 1897; past president of the Guilford County Medical Society; for many years health officer of High Point and member of the school board; veteran of World War I; served as trustee of the Agricultural and Technical College of North Carolina in Greensboro; died Jan. 5, aged 80, of cerebral hemorrhage.

McClellan, Wallace Roy, Akron, Ohio; Jefferson Medical College of Philadelphia, 1912; served during World War I; examining physician at Goodyear Tire & Rubber Company for many years; died in the Goodyear Hospital Jan. 15, aged 66, of rupture of aortic aneurysm.

McNamara, William E. ☉ Lansing, Mich.; University of Michigan Department of Medicine and Surgery, Ann Arbor, 1902; served as a member of the state council of health; fellow of the American College of Surgeons; past president of the Ingham County Medical Society; a founder of the People's State Bank; on the staff of the Edward W. Sparrow Hospital and St. Lawrence Hospital, where he died Jan. 19, aged 76.

Manning, Gustave Randolph ☉ New York City; Albert-Ludwigs-Universität Medizinische Fakultät, Freiburg, Germany, 1899; professor of gastroenterology at New York Polyclinic Medical School and Hospital; member of the National Gastroenterological Association, of which he was secretary; president of the Society for the Advancement of Gastro-Enterology when it was formed in 1933; served during World War I; on the staff of the Polyclinic Hospital, where he died Dec. 1, aged 79, of arteriosclerosis.

Marchildon, John Woods ☉ McClure, Ill.; Rush Medical College, Chicago, 1903; an Associate Fellow of the American Medical Association; member of the California Medical Association and the American Urological Association; formerly on the faculty of St. Louis University School of Medicine; died in Cape Girardeau, Mo., Jan. 29, aged 77.

Mayginn, Patrick Henry ☉ Tulsa, Okla.; St. Louis College of Physicians and Surgeons, 1897; an Associate Fellow of the American Medical Association; died Jan. 19, aged 82.

Miller, Arthur Weston ☉ Riverside, Calif.; University of Nebraska College of Medicine, Omaha, 1927; fellow of the American College of Surgeons; past president of the Riverside County Medical Society; served during World War II; on the staff of the Riverside Community Hospital, where he died Dec. 28, aged 50, of coronary sclerosis.

Moore, Samuel Barlow ☉ New York City; New York Homeopathic Medical College and Hospital, New York, 1901; affiliated with Metropolitan Hospital and Flower and Fifth Avenue Hospitals, where he was an alumnus trustee; formerly on the faculty of his alma mater; died Jan. 17, aged 74, of coronary disease.

Mueller, Emil F., Dyersville, Iowa; Northwestern University Medical School, Chicago, 1904; died in Sacred Heart Sanitarium in Milwaukee Jan. 22, aged 73, of coronary thrombosis.

Nibbelink, Benjamin ☉ Kalamazoo, Mich.; Detroit College of Medicine, 1912; died in the Bronson Hospital Jan. 10, aged 66, of myocardial infarction.

Nussbaum, Samuel Solis, Kingston, N. Y.; University of Maryland School of Medicine and College of Physicians and Surgeons, Baltimore, 1927; medical director of the Kingston public school system; affiliated with Kingston Hospital and the Benedictine Hospital; died Nov. 15, aged 52, of coronary thrombosis.

Oliver, Augustus Albert, Paris, Tenn.; University of Nashville Medical Department, 1910; for many years county health officer; died in St. Thomas Hospital in Nashville Jan. 11, aged 69, of heart disease and a kidney infection.

Oliver, Robert Byron, Idabel, Okla.; University of Arkansas School of Medicine, Little Rock, 1906; served during World War I; died Jan. 9, aged 81.

Pallister, Stanley Wilson, Bearsville, N. Y.; New York Homeopathic Medical College and Hospital, New York, 1898; fellow of the American College of Surgeons; for many years on the staff of the Carson C. Peck Memorial Hospital in Brooklyn; died in Woodstock Jan. 6, aged 77, of acute dilatation of the heart.

Pierson, Percy Raymond ☉ New Albany, Ind.; University of Louisville (Ky.) Medical Department, 1912; served overseas during World War I; on the staff of St. Edward Hospital; died in St. Joseph Infirmary, Louisville, Ky., Dec. 29, aged 65, of carcinoma of the lung.

Piper, Charles Leslie ☉ Vernal, Utah; University of Oklahoma School of Medicine, Oklahoma City, 1915; secretary of the Uintah Basin Medical Society; served during World War I; affiliated with Uintah County Hospital; died Dec. 21, aged 64, of coronary occlusion.

Proctor, Carter Atwater ☉ Sullivan, Mo.; Washington University School of Medicine, St. Louis, 1912; member of the American Academy of General Practice; died Dec. 29, aged 65, of coronary disease.

Richards, Thomas ☉ Glassport, Pa.; Jefferson Medical College of Philadelphia, 1926; president of the board of health; director of the Bank of Glassport; served on the staff of the McKeesport (Pa.) Hospital; died Dec. 30, aged 53, of coronary occlusion.

Robinson, Joseph Arnold ☉ New Bethlehem, Pa.; University of Pittsburgh School of Medicine, 1913; died in Western Pennsylvania Hospital, Pittsburgh, Nov. 26, aged 61, of heart failure.

Rodman, Nathaniel Fulford ☉ Norfolk, Va.; Jefferson Medical College of Philadelphia, 1914; member of the Southeastern Surgical Congress and the American Academy of General Practice; past president of the Norfolk County Medical Society; served during World War I; affiliated with Norfolk General, De Paul, and Leigh Memorial hospitals; died Jan. 14, aged 63, of multiple cerebral thrombosis and hypertension.

Rogers, Earl Bertram, El Paso, Texas; Northwestern University Medical School, Chicago, 1902; past president of the El Paso County Medical Society; affiliated with Hôtel Dieu, Sisters' Hospital; died in Southwestern General Hospital Dec. 31, aged 79, of carcinoma of the bladder.

Schilling, John Gaillard ☉ Houston, Texas; University of Texas School of Medicine, Galveston, 1909; fellow of the American College of Surgeons; on the consulting staff, San Jacinto Memorial Hospital in Baytown; on the surgical staff, Methodist Hospital; on the gynecologic staff, Memorial Hospital; on the visiting staff, St. Joseph's Infirmary; died Jan. 4, aged 68.

Scouller, John Samuel ☉ Philadelphia; Jefferson Medical College of Philadelphia, 1919; on the staff of the Northeastern Hospital; died Jan. 5, aged 60, of a heart attack.

Sinkler, Francis Wharton ☉ Bryn Mawr, Pa.; University of Pennsylvania Department of Medicine, Philadelphia, 1900; member of the American Neurological Association; past president of the Aid Association of the Philadelphia County Medical Society; formerly on the faculty of the Graduate School of Medicine, University of Pennsylvania, Philadelphia; served on the staff of the Episcopal Hospital in Philadelphia; died in Bryn Mawr Hospital Jan. 2, aged 76, after a fracture of his hip.

Sinkler, Wharton Jr., ☉ Philadelphia; University of Pennsylvania School of Medicine, Philadelphia, 1940; on the board and formerly chief resident physician at the Hospital of the Protestant Episcopal Church; served as resident at the Hospital of the Woman's Medical College of Pennsylvania; served during World War II; died Dec. 25, aged 39.

Sorensen, Jens, Detroit; Københavns Universitet Laegevidenskabelige Fakultet, Denmark, 1888; died Jan. 18, aged 86, of coronary occlusion.

Southwick, George Edwin, Chatham, Ill.; Miami Medical College, Cincinnati, 1892; died in the Memorial Hospital, Springfield, Jan. 19, aged 85.

Stewart, J. Sewell ☉ Pittsburgh; Hahnemann Medical College and Hospital of Philadelphia, 1919; served on the staff of Shady-side Hospital, where he died Jan. 19, aged 75, of a central nervous system lesion, type undetermined.

Taphorn, D. Henry ☉ Effingham, Ill.; Washington University School of Medicine, St. Louis, 1898; an Associate Fellow of the American Medical Association; for many years county coroner; served on the Effingham city council as commissioner of health and safety from 1923 to 1931; railroad surgeon for the Illinois Central and Pennsylvania railroads; died in St. Anthony's Hospital Jan. 14, aged 82, of myocarditis and intestinal obstruction.

Tomkins, Harry S., Los Angeles; Chicago College of Medicine and Surgery, 1917; died in Duarte Dec. 24, aged 67, of carcinoma of the esophagus.

Urevitz, Abraham ☉ New York City; University College of Medicine, Richmond, 1910; member of the Medical Society of New Jersey; served during World War I; affiliated with the Hospital for Joint Diseases; died in Union City, N. J., Jan. 13, aged 67, of coronary thrombosis.

Verta, John Camillo ☉ Schenectady, N. Y.; Regia Università di Napoli Facoltà di Medicina e Chirurgia, Italy, 1893; on the courtesy staff of the Ellis Hospital, where he died Oct. 2, aged 87, of pernicious anemia.

Waters, La Verne Francis ☉ Medina, N. Y.; University of Buffalo School of Medicine, 1908; served as county coroner and as health officer; on the staff of the Medina Memorial Hospital; died in the Buffalo General Hospital Jan. 13, aged 69, of embolism after an operation for hernia.

Weiss, Solomon A. ☉ Chicago; Chicago College of Medicine and Surgery, 1914; on the staff of the Belmont Hospital; died in St. Anne's Hospital Jan. 21, aged 63, of melanosis.

Worden, Rollin Duane, Ravenna, Ohio; University of Vermont College of Medicine, Burlington, 1915; served during World War I; formerly health commissioner of Portage County; during World War II served as a member of the selective service board and later as its medical examiner; died in the Lakeside Hospital in Cleveland Dec. 10, aged 64.

Yavorsky, George William ☉ Belle Plaine, Iowa; State University of Iowa College of Medicine, Iowa City, 1905; affiliated with Mercy and St. Luke's hospitals in Cedar Rapids; surgeon for the Chicago and Northwestern Railway; died in Cedar Rapids Jan. 7, aged 70, after pneumonectomy for bronchogenic carcinoma of the left lung.

Young, Roland Caldwell ☉ Toledo, Ohio; Rush Medical College, Chicago, 1921; president of the board of trustees of the Toledo Y. M. C. A.; affiliated with Flower Hospital, where he was past chief of staff, and a trustee, and Maumee Valley Hospital, where he was past chief of staff, Toledo, Mercy, and Riverside hospitals; consultant at Toledo State Hospital; died Jan. 7, aged 57, of coronary thrombosis.

DIED WHILE IN MILITARY SERVICE

Schorr, Harold Michael ☉ New York City; New York University College of Medicine, 1941; served as assistant professor of clinical medicine at his alma mater; specialist certified by the American Board of Internal Medicine; fellow of the American College of Physicians; affiliated with Bellevue and University hospitals; major, Medical Corps, U. S. Army; died in Camp Rucker, Ala., Dec. 16, aged 38.

Marvin, Theodore Richard ☉ Sarasota, Fla.; born in Jefferson, Ohio, Nov. 21, 1916; Ohio State University College of Medicine, Columbus, 1943; interned at the Naval and Southern Baptist hospitals in New Orleans; member of the Medical Association of the State of Alabama; initially appointed an ensign in the U. S. Naval Reserve in 1942; resigned this commission in May 1943 to participate in the Navy's V-12 medical training program; appointed a lieutenant (j. g.) in the Naval Medical Corps; became a lieutenant (j. g.) in 1944 and was promoted to lieutenant in the reserve in 1946; during World War II served in the Pacific in the USS LST-711, at Fleet Hospital no. 111 and Naval Base Hospital no. 18 and with Escort Division 7; released to inactive duty in June, 1946; became associated with the staff of the Perry County Hospital in Marion, Ala.; recalled to active duty in January, 1953, and ordered to the Naval School of Aviation Medicine, Pensacola, Fla.; designated a naval flight surgeon on completion of this course in June, 1953; ordered to the Marine Corps Air Station, Cherry Point, N. C.; last duty assignment was the Marine Air Group 11; died Dec. 30, aged 37, of injuries received in an automobile accident near Atsugi, Japan.

FOREIGN LETTERS

AUSTRALIA

Australia's National Health Service.—Until the establishment of the Commonwealth of Australia in 1901, all legislative powers resided with the six states (Queensland, New South Wales, Western Australia, Victoria, Tasmania, and South Australia), but, on federation, defense, mail and telegraphic service, and customs and excise rights were surrendered to the Commonwealth. The only health powers, however, that the states surrendered were those relating to quarantine. It was not until 1947 that the Commonwealth government obtained the power to make laws with respect to the provision of maternity allowances; widows' pensions; child endowment; unemployment; pharmaceutical, sickness, and hospital benefits; medical and dental services (but not so as to authorize any form of civil conscription); benefits to students; and family allowances. These powers were sought because three years previously the Labor government then in power had passed a Pharmaceutical Benefits Act designed to supply free to patients compounded and un-compounded drugs included in a government formulary, but the medical profession objected to the restrictions imposed by that formulary and other unacceptable provisions of the scheme. When the legislation was challenged by the Medical Society of Victoria, the High Court of Australia (corresponding to the United States Supreme Court) declared the legislation to be outside the powers of the Commonwealth parliament. In 1948, under the increased powers obtained by referendum, the Labor government passed similar legislation, but again the medical profession refused to participate. Subsequently, when the government attempted, under amended legislation, to use coercive powers, the High Court was again approached and it held that such coercion entailed a measure of civil conscription and the enactment was, therefore, invalid. There the matter remained until 1950.

Although the government in 1948 passed a National Health Service Act, under which it would have been possible to establish a complete national medical service free to the patient and paid for out of social service taxation, no action was taken under the legislation. In 1949 the Labor government was defeated and succeeded by a coalition government of Liberal (conservative) and Country (farm) party members led by the present prime minister. Sir Earle Page, a physician, was appointed Minister for Health, and soon after he announced that the government would encourage voluntary health insurance, using its funds to amplify the coverage against sickness provided by approved insurance organizations. He has received the cooperation of the medical and pharmaceutical professions in developing his plans. The following steps have been taken:

1. By arrangement with the state governments each school child under 12 years of age receives free one-third of a pint of milk per day, and in remote areas where fresh milk is not available powdered milk is supplied.

2. In July, 1950, a scheme of tuberculosis allowances was brought into operation and sufferers from the disease, while undergoing treatment, are paid cash allowances. The Commonwealth government also contributes to the cost of mass x-ray surveys conducted by state health departments and to the capital costs of construction of sanatoriums.

3. In September, 1950, a substantial list of lifesaving and disease-preventing drugs was made available free to all citizens. They are supplied to patients by approved druggists on the prescription of a physician, and the government pays the druggist. Included in the list are the sulfonamides, insulin, penicillin, streptomycin, chloramphenicol, chlortetracycline, vaccines, serums, and many other drugs of proved value, and additions to the list are made from time to time on the recommendation of a pharmaceutical benefits advisory committee, on which the medical and pharmaceutical professions are represented.

4. In February, 1951, a free medical service for aged, invalid, and widowed pensioners, and their dependents, including about 600,000 persons, was introduced. Under this service beneficiaries receive free of cost from participating physicians, any physician being eligible to participate, those services customarily rendered by a general practitioner in his office or in the patient's home. In addition to the drugs available free to all citizens, they may receive, on prescription and without cost, any drug in the British Pharmacopoeia, either alone or in combination. There is no contract between the government and the physician, but by arrangement with the Federal Council of the British Medical Association in Australia, those rendering service charge concessional rates (9 shillings a consultation and 11 shillings a domiciliary visit or about 60% of private charges). Payment is made to the doctor by the health department on production of vouchers signed by the patient, who certifies that he has received service and requests that payment be made to the doctor by the government on his behalf.

5. In July, 1953, a medical benefits scheme was started, under which the amounts payable in return for premiums by organizations offering insurance against the costs of medical care are supplemented by subsidy from government funds paid through those organizations. Commercial insurers are excluded from the scheme, and only mutual nonprofit organizations are approved, one of the conditions of approval being that the insurance organization must pay to its contributors an amount not less than the government subsidy as set out in a table of subsidies, but in no case shall the total benefit exceed 90% of the physician's account. In that way a personal obligation to meet part of the cost of medical care is imposed on the contributor, thus safeguarding available funds against abuse. As an additional safeguard payment is made by a benefit organization only on production of a physician's receipt, except in cases of hardship, when benefits may be paid before the patient has paid his physician. The amount of the subsidy varies in relation to the nature of the medical service, but for any particular service it remains the same whatever actual fee the physician charges, whether the service is rendered by a general practitioner or a specialist. The table of subsidies lists nearly 1,000 items covering the whole range of medical practice, including consultations, operations, obstetrics, radiological service, and pathological study.

For about 10 years benefits have been paid by the Commonwealth at the rate of 8 shillings a day to all persons occupying hospital beds, but voluntary insurance against hospital costs is now being supported by the payment of an additional 4 shillings a day to members of hospital benefit organizations, usually, in fact, the same organizations that offer coverage against the costs of medical care.

Because the present government did not have a separate majority until May, 1953, it hesitated to introduce new legislation that a hostile upper house would reject. Consequently the foregoing plans were developed by the promulgation of regulations under existing legislation—the Pharmaceutical Benefits Act and the National Health Service Act of 1948—but in December, 1953, the National Health Act was passed. That measure has established a firm legal basis for the services now in existence.

It will be seen that, unlike Great Britain on the one hand with a nationalized medical service and the United States on the other hand with its predilection for personal responsibility, Australia has adopted a middle course, a system of self-help aided by the resources of government. The last six months have shown that the public reaction is favorable to the proposals, as during that time there has been a vast increase in membership of insurance organizations, and already at least half of the Australian population is covered by voluntary insurance against some part of the costs of illness.

ECUADOR

Hemodynamic Changes in Anemia.—Drs. Lanari, A. García, and C. Nuñez of Guayaquil reported on the hemodynamic changes that occurred in a group of men with tropical anemia of various degrees of intensity, but without cardiac, pulmonary, or infectious diseases. The quantity of hemoglobin in the blood of all patients varied between 1.7 and 8 gm. per 100 cc. The authors reported the following observations: 1. The blood volume of these patients was diminished in proportion to the quantity of hemoglobin. This diminution was of moderate intensity when the hemoglobin level was more than 6 gm. per 100 cc. It was marked when the quantity of hemoglobin was less than this. The lower the quantity of hemoglobin, the greater the diminution in blood volume. When the hemoglobin fell to 1.7 gm. per 100 cc., the blood volume diminished to about 25% of normal. 2. The amount of oxygen in the arterial and venous blood in these patients was below normal. When the hemoglobin was 8 gm. or more per 100 cc., the saturation of arterial blood was 100%. When the hemoglobin was less than 8 gm. per 100 cc., the blood was not saturated with oxygen. The degree of saturation decreased as the hemoglobin diminished down to 6 gm. per 100 cc. At this figure, saturation was about 80%. Further diminution of hemoglobin did not decrease the degree of saturation. 3. The so-called "cardiac index" increased in proportion to the diminution of hemoglobin. Thus, an index of 5.5 when the hemoglobin was 8 gm. per 100 cc. increased up to 9.8 when the hemoglobin fell to 1.7 gm. per 100 cc. 4. The velocity of circulation increased with the diminution of hemoglobin. The normal velocity was doubled when the hemoglobin dropped to 1.7 gm. per 100 cc. 5. The pulmonary ventilation in these patients was increased but this may normally show variations due to the emotional condition of the patients during the examinations. Pulmonary hyperventilation was marked when these patients were subjected to physical exercises. This hyperventilation was greater in patients with hemoglobin levels less than normal, and in such patients it lasted longer after physical exercises. 6. The pulse and respiratory rate were increased when the hemoglobin fell below 8 gm. per 100 cc. Thus, a pulse rate of 80 when the hemoglobin was 8 gm. per 100 cc. may increase to 120 when the hemoglobin falls to 1.7 gm. per 100 cc. 7. The minute volume of circulation increased as the hemoglobin decreased. When the hemoglobin fell to 1.7 gm. per 100 cc., the minute volume was triple the normal figure and it increased to even six times normal after physical exercise. 8. The volume of blood expelled from the heart with each systole was also increased and increased still more after physical exercise in these patients. (*Gac. méd. Guayaquil* 8:397, 1953).

Blood Groups in Indians of Ecuador.—Before the Spanish Conquest, the Indian population of the coastal, Andean, and Amazonian regions of Ecuador consisted of several races that have now almost disappeared. Only a few groups of descendants of two of the coastal and three of the Amazonian races are still found, whereas the Indian population from ancient Andean races is very large, especially in the high plateaus of the Andes. The Indian population comprises 16% of the total population of the country. In a racial sense, the Indians are isolated from the rest of the population. They live in zones 10,000 ft. or more above sea level and do not mix with the white population. The contrary is observed in cities of the lower zones, where mestizos predominate as a result of several generations of marriages between the Spaniards and Indians. Dr. A. Santiana, professor of anthropology of the Central University of Ecuador, carried on extensive researches on the blood groups in Indians. Of 8,112 Andean Indians, 7,707 (95.01%) had blood that corresponded to group O; 290 (3.57%), to group A; 94 (1.16%), to group B; and 21 (0.26%), to group AB. Of 1,055 Amazonian Indians, 1,036 (98.20%) had blood that corresponded to group O; 17 (1.61%), to group A; 2 (0.19%), to group B; and none, to group AB. Of 150 coastal Indians, who are probably of the same somatic Andean type, 100% corresponded to group O. The results were probably due to the small number of Indians in this group. Probably Indians of groups A and B could have been found in a study of larger groups of coastal Indians.

Antihistaminic Agents for Burns.—The antihistaminic agents have local anesthetic properties. Some antihistaminics are more effective than procaine. These substances, used in the prevention and in treatment of solar erythema and of erythema due to ultraviolet radiations, give good results. One of the antihistaminic agents Dr. P. Naranjo used in treating burns due to heat and chemical substances was pyrilamine (Neo-Antergan). He applied a solution of 0.1 to 0.5% of the antihistaminic agent over the burn every 15 or 30 minutes until the pain was relieved. Then he applied an antihistaminic salve daily for one to three days. The pain was usually controlled within 30 minutes after the first application of the solution. Thereafter only a slight pain was reported by the patients. When the antihistaminic agents are applied in the first minutes after the burn, blisters and edema of the skin are prevented. If blisters are already formed, they reabsorb within 24 hours. If secondary infection occurs, the well-established treatments for infection should be used (*Gac. méd. Guayaquil* 8:414, 1953).

FINLAND

Campaign Against Tuberculosis.—With a population of 4 million, Finland has only 13.5 inhabitants per square kilometer. This thin distribution of the population partly explains some of the features peculiar to the behavior of tuberculosis in the country, but on the whole the campaign against this disease has followed a pattern closely resembling that of other European countries, especially Denmark, Norway, and Sweden. As in these countries, voluntary activities have gradually been taken over by the state and local authorities in an attempt to secure more effective centralization. In 1944 a state tuberculosis committee was appointed to draft new legislation for the control of this disease. The recommendations of this committee led to a new law, which became operative in 1949 and provided for the partition of the country in 19 tuberculosis districts under the administration of the Ministry of Health. Each such district is required to maintain a tuberculosis bureau and a sanatorium. Special institutions must be provided for occupational therapy, for children threatened by tuberculosis in their homes, and for refractory patients. BCG vaccination is not compulsory, but everyone who has reached the age of 15 must submit to a medical examination at his local bureau unless he can present a medical certificate, not more than three months old, by a lung specialist exempting him from examination. BCG vaccination was started in 1941, but during the next few years little use was made of it, and only about 25,000 persons had been thus vaccinated up to 1944. In 1951 a total of 123,063 persons were vaccinated with BCG, and the total number of such vaccinations has risen to about one million. In spite of this vaccination being voluntary, nearly every newborn infant is now vaccinated with BCG, the reaction being subsequently tested with tuberculin at a tuberculosis bureau. Tuberculin testing is repeated at the time of entering school, and BCG vaccination is repeated when necessary. Since 1943 almost every tuberculin-negative man called up for military service has been vaccinated with BCG provided by a bacteriological laboratory in Gothenburg. The Tuberculosis Association, founded in 1941 by the patients themselves, has grown into a powerful organization with about 30,000 members and both the will and the means to give the victims of tuberculosis substantial help. In 1953, this association opened a high school with accommodation for 52 pupils. A center for the re-education of tuberculous war invalids has also been provided by this association.

Crude Liver Extracts for Cirrhosis of the Liver.—The work of Hoagland, Ralli, and others in the United States on cirrhosis of the liver treated by intravenous injections of crude liver extracts has been closely followed in Finland where two studies of this problem have been undertaken by Dr. Gustaf Østling and Dr. Erik Adlercreutz respectively. The first tests were not as encouraging as the more recent ones. A crude liver extract called neoheptomin did not at first contain much vitamin B₁₂ but the later batches contain a large amount of this vitamin. Both these studies are published in *Nordisk medicin* for Nov. 26, 1953, and although Østling's is chiefly concerned with general principles and a review of the literature, the study by Adlercreutz deals

with concrete experiences in Helsingfors, where about 30 patients with hepatic disease have been given this treatment. He is chiefly concerned with 10 of these patients in whom the response to intravenous injections of neoheptomin was most instructive. Eight of these patients had Laennec's cirrhosis. Adlercreutz notes that admission to a hospital, with its attendant rest and dietetic treatment, often by itself effects great improvement and so obscures the issue. In 8 of the 10 patients, however, the marked diuresis that occurred soon after the intravenous injections were started pointed to their being effective in themselves. In one patient ascitic fluid disappeared completely, but the most striking effect was the improvement in the patient's general condition. In two patients the injections had to be discontinued for a week or more because of fever, but after this interval the treatment was resumed without any further complications. To avoid a sense of heat in the face during the injections it was found desirable to give them very slowly. Adlercreutz was puzzled over the character of the active principle in crude liver extracts, and he has found no great difference of potency in the original neoheptomin, which was poor in vitamin B₁₂, and that of the later batches, which contained more of this vitamin. He also could find no marked difference of effect resulting from varying the size of the doses. This treatment may prove to be a valuable auxiliary to preoperative and postoperative treatment. In his more recent cases Adlercreutz has found it desirable to reduce the chances of a violent reaction by giving neoheptomin by drop infusion with 100 to 200 ml. of a glucose solution.

ISRAEL

Side-Effects of Penicillin.—In the fall of 1953 in a four week period 13 cases of cutaneous reaction due to penicillin were observed by I. Katzenellenbogen of the Central Department for Skin Diseases of the Workers' Sick Fund in Jerusalem, as reported in the *Harefuah*, Dec. 15, 1953. Seven men and six women aged 17 to 47 were treated. All but two previously had received penicillin; four by injection and seven by ointments and lozenges. In three, papulovesicular eruptions developed on the palms, soles, and genitocrural regions. The eruption appeared 24 to 36 hours after the first injection. Three patients presented a generalized urticaria, appearing between 7 and 10 days after penicillin treatment and lasting from 7 to 14 days. In seven patients a combination of an immediate and delayed reaction occurred, beginning a day or two after the injection with a delayed serum sickness developing 10 to 17 days later. In one patient, with no previous history of fungous disease, a severe papulovesicular rash appeared on the palms, soles, and axillary and genitocrural regions and was preceded by perleche and an erythematous rash on the chin. No fungus was found either microscopically or by culture. Intradermal tests of sensitivity to penicillin and trichophytin in this case were positive. In two patients the eruption occurred after a single injection, the local reaction appearing after 24 hours and generalized urticaria with angioneurotic edema 17 days after the injection. In four patients otolithic vertigo was observed with alteration of the caloric reaction. In one patient with a severe delayed serum sickness cortisone relieved the polyarthritis, the high fever, and the urticarial rash, without influencing the vertigo. In the same patient an eruption developed on previously tanned parts of the body.

Seven of 11 intradermal tests with 2,000 units of crystalline penicillin were positive, but patch tests with procaine penicillin and crystalline penicillin were negative in all patients. Only 2 of 11 tests with trichophytin were positive. The Prausnitz-Kustner reaction was positive in one of three patients tested. Dermographism was observed in all urticarial cases; hyperhidrosis, only in two.

Possible causes of so many penicillin reactions in a short period include (1) previous or currently existing mycosis, (2) indiscriminate use of penicillin ointment, lozenges, etc., (3) the allergic condition of the patient, and (4) the brand of the drug. The author recommends avoiding the local use of penicillin or its injection without proper indication. It is suggested that in suspected cases antimycotic and antihistaminic treatment be given at the same time as the penicillin injections. Cortisone was helpful in severe cases of delayed serum sickness.

Scholarships for Medical Students.—The central committee of the Medical Association proposes to maintain 10 scholarships in the amount of 300 Israeli pounds per annum each, out of contributions from physicians all over the country. This undertaking was prompted by both the difficult economic position of the students already studying in institutions of higher learning and the fact that the number of young physicians is extremely small compared with that of older ones. In several branches of medicine, there is a danger that in 5 or 10 years a patient may have to wait several months for a tonsillectomy or an orthopedic operation. Members of the Workers' Sick Fund have already been queuing up six months or longer for such operations. At the end of 1952 about 48% of all physicians in the country were over 52 years old, while the number of physicians under 36 years of age did not exceed 12%. The position is particularly acute in specialized branches; about 65% of the dermatologists, 60% of the radiologists, 62% of the ophthalmologists, 52% of the psychiatrists and neurologists, 50% of the otolaryngologists, 54% of the gynecologists, 52% of the pediatricians, and 51% of the internists are 50 years old or over. Only 8% of the otolaryngologists, 10% of the dermatologists, 11.5% of the radiologists, 11% of the ophthalmologists, 19% of the psychiatrists and neurologists, 22% of the pediatricians (mostly women), 16% of the gynecologists, 17% of the internists, 23% of the general practitioners, and 25% of the surgeons are under 40 years of age.

Since the establishment of the state of Israel in 1948, the population of the country has more than doubled, but owing to the composition of the mass immigration, which has derived chiefly from depressed countries, only 1,008 physicians have entered the country during this period. These now constitute 29.4% of the total number of physicians in Israel. Only 106 physicians have come from Egypt, Tunis, and other parts of Africa. It is encouraging, however, that most of the immigrating physicians have been young. Of the 684 physicians in the country who are not more than 41 years of age, 587 immigrated to Israel after the establishment of the state.

TURKEY

Idiopathic Anemia.—In *Dirim*, vol. 28, no. 3, Prof. Zeki Hakki Pamir and Dr. Cavit Sökmen described a case of idiopathic aplastic anemia. Of 4,826 patients admitted to Professor Pamir's clinic from 1946 to 1952, 228 had blood diseases. This first patient with idiopathic anemia seen in the clinic was a 17-year-old girl who, on admission, was very pale and complained of weakness, headache, palpitation, and bleeding of the gums. Following injury, external hemorrhage was arrested with difficulty. The patient weighed 56 kg., had a regular pulse rate of 92, and a blood pressure of 105/75 mm. Hg. Her liver and spleen were soft and of normal size. She had a cardiac souffle, bleeding of the gums, and ecchymotic spots on the skin. Her gastric secretion was normal. Her parents and three siblings were in good health. The coagulation time was 8 minutes, the bleeding time 30 minutes, the erythrocyte count 1,540,000, and the leukocyte count 3,000 per cubic millimeter, with 71% lymphocytes, 25% immature forms, 2% eosinophils, and 2% monocytes. The hemoglobin level was 5.5 gm. per 100 ml.; the thrombocyte count was 11,620; and there were 1.16% reticulocytes. The myelogram showed 45% lymphocytes, 18% normoblasts, 9% myeloblasts, 9% transitional cells, 8% monocytes, 5% macroblasts, 4% immature forms, and 2% reticulocytes. Results of the epinephrine test for hypersplenism and the blood plasma-modium, Wassermann, and urobilinogen tests were normal. Results of the bilirubin test of the blood by the direct method were normal and by the indirect method revealed 0.04 mg. per 100 cc. Iron and liver extracts, vitamin B₁₂, folic acid, and cortisone did not benefit the patient who during her 110 days in the hospital was given seven blood transfusions. Following a transfusion the erythrocyte count increased to about 2 million cells per cubic millimeter, but decreased again after one week. The patient refused splenectomy and left the hospital.

CORRESPONDENCE

DECELERATION AND THE MOTOR CAR

To the Editor:—In this age of increasingly rapid transportation, the one hope of survival is the control of deceleration. In a paper appearing in 1946 Hugh DeHaven stated, "Up to the present, aircraft have been built solely to fly, not to crash. This single approach and design has been costly in the past and is no longer acceptable in military aircraft where a few pounds of extra weight to give crash protection has been an important concession." The modern military aircraft is built around a safety island. The wings, tail, and motor may all separate but this island remains intact and will resist impacts beyond 40 G. In this island the personnel are fastened with harness and belts designed to withstand 40 G. or more. Personnel survival in airplanes so constructed is many times greater than in the type of planes flown in World War II.

On our highways, too, we must learn to control rapid deceleration. As the speeds of motor cars have increased we have progressed through brakes on the rear wheels, four wheel brakes, and now we have reached the point of diminishing returns as far as deceleration is concerned. I have heard two motorists state, "You sure have to be careful with these power brakes, I threw my wife into the windshield twice until I learned to use them." In other words, the potential stopping power of power brakes cannot be utilized because the motor car manufacturers have not installed devices to keep the passengers in place when modern brakes are used. Where the aviation industry has met the problem with boldness and originality, the motor car manufacturers have done almost nothing to protect the persons riding in motor cars when they must decelerate rapidly. We have lost between 30,000 and 40,000 lives on our highways each year since 1915, and the number of injuries, ranging from minor to the most disabling, number over one and one-half million each year. Is this inevitable? Are we who made the machine necessarily a victim? Let us consider this problem a moment. When a motor car hits a pedestrian, that victim is hurt, his injury is immediate. The traffic engineers must increasingly separate the streams of motor traffic from pedestrian traffic just as we have at long last separated motor traffic from the railroad train. On the other hand, when two motor cars collide or when a motor car meets a fixed obstruction, no one is hurt. The bridge abutment is dented and the front of the motor car is bashed in, but the safety island in the center of the car is intact, no one is hurt. The forces have all been applied to inanimate objects. Not until the occupants began slamming around inside the car or hurling themselves against objects outside the car do they receive injury. Can these injuries be prevented? In accidents of comparable degree affecting modern military aircraft, the personnel walk away with hardly a scratch. In stock car races the drivers put their cars into worse spills than often occur on the highway, and regularly they step out of the car, wave to the crowd, and walk away. Mr. William W. Harper describes it in phrases of the utmost clarity: "Let us assume that a vehicle collides with a solid fixed object at a speed of 30 miles per hour. Let us assume further that the car is crushed in a distance of two feet. This means that the velocity of the vehicle has decelerated from 30 miles per hour down to zero in a distance of two feet. This represents a deceleration rate of 483 feet per second per second. Such a deceleration is 15 times the acceleration of gravity, which is 32.2 feet per second per second. This unit of gravity is called the G. For convenience, we say that the vehicle suffered a 15 G. crash. But how does the vehicle occupant behave in such a crash? At the moment of impact he has the same velocity as the vehicle. As the vehicle crashes to a full stop he continues forward at almost the same speed of 30 miles per hour and collides with the dash and windshield. By the time his body reaches those objects they are at rest, or nearly so. Assuming that the combined crushing of his body and vehicle interior will reduce his velocity to zero in a distance of two inches, he will have suffered a deceleration of almost 5,700 feet per second per second, or 176 G. Although the occupant might have survived without injury the 15 G. crash

of the vehicle, he cannot escape injury or death from the 176 G. crash of his body against the interior of the vehicle. The physics of injury tells us something which seems paradoxical: If the occupant wore the car, as he would a suit of armor, the crushing of the car exterior in a collision would absorb tremendous amounts of impact energy and protect him from bodily injury. The occupant would be spared injury unless his passenger space became extensively crushed. But for some unexplained reason the teachings of physics have never been understood or accepted by the motorist—so, rather than 'strap on' the vehicle and take advantage of its protective armor in a crash, the motorist watches the vehicle crash relatively slowly to a stop and then dashes himself violently to pieces against its interior! This makes no sense at all, but it is still standard practice after 50 years of automotive accident history."

The Colorado State Medical Society adopted the following resolution and sent it to all the motor car manufacturers in the United States and to all the other state medical societies urging them to make similar resolutions: "Whereas motor car deaths in the United States of America number between 35,000 and 40,000 annually and motor car injuries number about one and a half million annually; and whereas there seems little likelihood of any great reduction of motor accidents in the near future; and whereas studies by physicians and physicists have clearly shown that motor injuries and motor deaths can be strikingly reduced by the use of safety belts and safety shoulder straps, therefore be it resolved: That the Colorado State Medical Society will give all possible aid to those measures which will reduce the frightful mortality and injury rate resulting from the use of motor cars, and be it further resolved: That the Society hereby recommends to the motor car manufacturers of America that they equip all automobiles with safety belts to meet the specifications of the C. A. A. Technical Standard Order, T. S. O.-C22 A, November 15, 1950, and further recommends that these manufacturers provide seats, cushions, and doors which will withstand impacts of 10 to 15 G. without injuries."

Poliomyelitis took 3,300 lives in 1952. The motor car took 10 times as many. Poliomyelitis injured 14,000 persons in 1952. The motor car injured 100 times as many. Our motor car manufacturers must build the automobile to crash. An active program resulting in safety belts for every motor car occupant can save more lives per dollar than anything else we can do.

Denver.

CHLOROPHYLL

To the Editor:—I wish to reply to several points raised in this section, Oct. 24, 1953, dealing with chlorophyll. These points stemmed in part from my earlier letter on this subject in the June 27, 1953, and in part from an editorial in the Aug. 29, 1953, issues of THE JOURNAL.

I paid commercial chlorophyll derivatives the compliment of being pheophytins or pheophorbides. This placed them nearer in structure to chlorophyll than they actually are. It now develops that in reality they consist of chlorin e and rhodine. These compounds are more broken down than pheophorbides in that one of the five rings, which constitute the normal structure of chlorophyll, has been opened. In this, by the way, Dr. Westcott was misled when he said that "The removal of magnesium from 'chlorophyllin' does not lead to pheophorbides but to chlorins"; the removal of magnesium does lead to pheophorbides and the chlorin results only from an additional breakdown reaction by alkali (Fischer and Stern, 1940). The commercial "derivatives," therefore, have had removed from them the magnesium, the phytol, and the methyl alcohol; in addition one ring has been broken and an atom

of copper has been added. It follows that the term chlorophyllin, still less chlorophyll, should no longer be applied to these materials. They should be called what they are, namely copper chlorins. It is as though one were to split the molecule of vitamin B into its two constituent parts, break off the side-chain, substitute the sulfur atom for something else, and then market the material as "vitamin B derivative." I think most nutritionists would agree that such nomenclature would be misleading and dangerous.

Dr. Langley says I ignored a paper he presented at the Federation meetings in April. My letter was written on Feb. 16. I now have certain criticisms of his paper; they are as follows. In the first place, hydrogen sulfide-air-water mixtures are notoriously unstable and are oxidized to sulfur at a moderate rate merely on standing; the reaction is probably catalyzed by heavy metal ions, so that rigid controls would be needed to establish an effect due to copper chlorin. In the second place, the copper chlorin would contain enough copper to react chemically with an appreciable fraction of the hydrogen sulfide. Langley's data suggest that about 0.25 mM. of hydrogen sulfide reacted with 30 mg. of copper chlorin, the copper content of which is not stated. In the third place, no mention is made of comparative tests on other copper-containing compounds or on other catalysts; ferric chloride, for instance, is very active in this oxidation. Last, it does not seem probable that the oxidation of hydrogen sulfide has any close relationship to the deodorization of organic bases, such as skatole, that are not readily oxidized and contain no reactive sulfhydryl group.

These considerations raise the problem of what deodorization really means, in a biochemical sense. Odors that are considered disagreeable may arise from substances of extremely varied chemical constitution. Some of these can be oxidized, some can perhaps be adsorbed on active surfaces, and some can perhaps be precipitated or removed in other ways. A given substance, therefore, might well deodorize chemicals of a certain type and yet be quite unable to affect others. The idea of a general deodorant is difficult to justify since no general reaction is involved.

I must say that it is interesting that responsible workers such as Harrison and Langley are now trying to obtain evidence that copper chlorin does actually deodorize. It would have been better to have done this first, before putting the material on the market. Usually research on the value of a therapeutic agent is done before, rather than after, its sale to the public.

HEMOPHILIA AND CLOTTING TIME

To the Editor:—The findings of Brinkhous and his associates (Newer Approaches to the Study of Hemophilia and Hemophiloid States, *J. A. M. A.* 154:481 [Feb. 6] 1954) that hemophilia may range in intensity from severe to subclinical, that the clotting time may be normal in the mild type, and that the antihemophilic factor appears to remain fairly fixed in any one patient with hemophilia confirm our earlier observations, the importance of which we have repeatedly emphasized (*Pediatrics* 3:312 [March] 1949; *Am. J. M. Sc.* 223:401 [April] 1952). They likewise stress the difficulty of diagnosing the mild type of hemophilia. Among the tests they employ is a one stage prothrombin time of serum, a test slightly modified from the original that I developed and reported in 1947. Recently, we described a new test that we have designated as the thromboplastinogen activity time (T. A. T.). (Quick, A. J.; Stapp, W. F. and Hussey, C. V.: *J. Lab. & Clin. Med.* 39:142 [Jan.] 1952). In a series of over 100 persons with hemophilia, we have found this test reliable, even when the disease is exceedingly mild. The procedure has the added advantage of great simplicity.

While it is the prerogative of an investigator to devise his own schemes, outlines, and classifications, one may, nevertheless, question whether a condition such as labile factor deficiency should be shifted from the category of hypoprothrombinemia and pseudohypoprothrombinemia to the hemophiloid group and be named hemophiloid state A as Brinkhous and his associates propose. In the past, it has been convenient and helpful to the

clinician to divide the hemorrhagic diseases into those with a prolonged and those with a normal prothrombin time. Characteristically, hemophilia and hemophilia-like conditions have a normal, while labile factor deficiency has a prolonged prothrombin time. In any consideration of hemophilia-like states, the disease produced by a circulating anticoagulant seems to warrant not only inclusion but an important position in the classification. We have obtained fairly conclusive proof that the anticoagulant is an antithromboplastin and that the condition, therefore, may be called antithromboplastinogenemia. The disease is important, first, because it is easily mistaken for true hemophilia and, second, because it does not respond to transfusion even of fresh blood. While the newly reported aberrant types of hemophilia are still mostly ones of academic interest, antithromboplastinogenemia presents a problem that any clinician may be confronted with unexpectedly.

SANATORIUM TREATMENT FOR TUBERCULOSIS

To the Editor:—Is sanatorium treatment for pulmonary tuberculosis necessary? The current trend in the treatment of pulmonary tuberculosis is away from the use of sanatoriums. Two hopes are responsible for this; first, that drug therapy will prove to be a specific cure for tuberculosis and, second, that bed rest is either no longer needed or can be taken as well at home. It is already quite clear that the first of these hopes is unfounded. Even the most complete program of chemotherapy plus rest, collapse, and resection has failed to control some cases. Chemotherapy plus rest alone has likewise failed in at least 10% of those persons with moderately advanced and 40% of those with far advanced disease. The question of whether chemotherapy with or without rest will prove to be curative for favorable types of tuberculosis will require several more years of observation of initially successful cases. As regards the hope that bed rest is not needed to treat pulmonary tuberculosis, a review of our knowledge of the subject is considered pertinent.

Since it was originally introduced at the turn of the century, there has been little doubt of the value of bed rest in the general management of pulmonary tuberculosis. As time passed, its practice became standard. Its use reached a peak when 24 hours a day in bed for four to eight months or more was recommended for asymptomatic, early minimal lesions. After a half century of its use, our knowledge of how bed rest works and of how much is needed in the individual case is scanty indeed. Furthermore, because of great advances in treatment, new data on unaided bed rest will not be available. From what information we have, however, we may assume that the action of bed rest is twofold—rest and the horizontal position.

Physical rest is the most obviously effective aspect of bed rest. Rest reduces movement of the diseased lung by lowering body metabolism and oxygen requirements. Rest also probably promotes nonspecific resistance against infection, thus augmenting the bacteriostatic effect of drugs. While there can be no doubt of the importance of rest, there has been disagreement over its strictness and duration. For instance, no relationship was found between duration of modified bed rest before chemotherapy and the long term behavior of minimal tuberculosis when 589 cases were analyzed retrospectively (Mitchell: *Am. Rev. Tuberc.* 67:401, 1953). The results were superior to those observed in a similar though untreated group (Reisner and Downes: *Am. Rev. Tuberc.* 51:393, 1945). Furthermore, in comparable groups of patients with minimal disease, De Friez and associates have found results about the same with strict as with modified bed rest. Can it be that we have prescribed excessive bed rest through lack of a more specific treatment?

Maximum rest is not always attained by spending 24 hours a day in bed. Some patients are more apt to obtain physical rest in a sitting or semireclining rather than recumbent position or by mixing periods of reclining with various mild ambulant

activities. This becomes a necessity in elderly or emphysematous patients for whom strict bed rest is frequently harmful. Rest of the mind is achieved by light reading, inconsequential conversation, pleasant contemplation, or just doing nothing. Rest of the emotions requires, in particular, the avoidance of responsibilities and personal problems. Such optimum physical, mental, and psychological rest is usually not attainable in the average home but may be found in the sheltered and simplified environment of a good sanatorium.

The second bed rest factor, the horizontal position, can, of course, be accomplished in the home as well as in the sanatorium. It has been suggested that the pulmonary circulation in the upper lungs may be virtually nil in the upright position; poor circulation adjacent to well-ventilated alveoli thus produces an alveolar environment rich in oxygen and poor in carbon dioxide, known to be favorable to the growth and multiplication of tubercle bacilli (Dock: *Am. Rev. Tuberc.* 53: 297, 1946). This concept has now been supported by Scott in animal and by Martin, Cline, and Marshall in human experimentation. The hypothesis that oxygen lack favorably influences a tuberculous lesion is supported by the observation that persistence of air-containing cavity has been associated with most failures of modern chemotherapy. Furthermore, Wright Place, and Princi have observed that there is 10 to 40% less air in the lung in the recumbent than in the erect position, making the recumbent position a minor bilateral lung collapse.

Perhaps the most vital contribution made by the good sanatorium today, and not always clearly recognized, is the education of the patient. The patient who is put to bed in a sanatorium is first given encouragement and hope; in addition, he is taught respect for a relapsing and contagious disease, a respect made necessary by the undue optimism generated, in particular, by the lay press. Day after day physician and nurse will be able to impress him, individually and in groups, with the necessity of acquiescing to his disease, at least temporarily, and, in appropriate cases, of managing his later life in accordance with his condition. Above all, the patient is impressed with the importance of taking for a long period, and without interruption, drugs that not infrequently cause unpleasant side-reactions. These reactions, whether hypersensitivity, toxicity, or intolerance, have led patients or their physicians to stop or interrupt the use of one or more drugs, thus greatly increasing the risk of loss of benefit and the emergence of drug-resistant bacilli. Unless the patient fully understands the alternative to a successful outcome of treatment, he cannot be expected always to cooperate in a prolonged, often tiresome and unpleasant routine. The time required for this education is determined more by the personality and intelligence of the patient, than by the nature and extent of the disease. As evidence of the truth of what he is taught, the patient will see around him other patients who have benefited by their training and still others who have failed to control their disease through lack of it. It is quite likely that this contact with other patients, or the knowledge gained by experience, so to speak, is the most important aspect of sanatorium treatment today. It is for these reasons that a new patient can seldom be educated as effectively in bed at home or in a physician's office, even when the physician has a thorough and up-to-date knowledge of tuberculosis.

A final but important point is segregation of an infectious case of tuberculosis, still an important public health consideration. Most new patients, when properly treated, will be non-infectious in from one to six months after starting treatment, but not all. And good cough and expectoration habits can be taught most effectively in "classes" and under continuous professional observation at the sanatorium.

There is the possibility that certain select but as yet undefined patients may not require rest because of modern chemotherapy. A 2 to 12 month period of observation may be necessary to select these favored persons. This observation may be conducted most profitably in a sanatorium. There are others whose disease is such that we know at diagnosis that chemotherapy will not do the whole job. For such patients, as well as for indigent and custodial patients, sanatorium treatment and all its adjuncts are as necessary now as ever. Whatever the prognosis seems to be, however, a period of education and orientation is important to all new patients; this is accomplished

best in the sanatorium. Despite drastic improvements in treatment, the sanatorium still plays a vital part in dealing with pulmonary tuberculosis.

Clinical Director, Trudeau Sanatorium
Trudeau, N. Y.

INTERNATIONAL HEALTH

To the Editor:—The article "Opportunities and Responsibilities of the Physician in World Affairs" by Dr. Trimble in the Nov. 28, 1953, issue of THE JOURNAL is extremely timely and acutely points up an area of new responsibility for physicians. The promotion of health abroad has become an integral part of United States foreign policy based on the concept that poverty and mass illness are interrelated. Today the United States is spending an estimated 51 million dollars on international health programs through several agencies. Organized medicine must undertake responsibilities lest health programs be developed without benefit of the best medical knowledge.

One of the foremost deficiencies is the lack of personnel adequately trained to deal with the exotic diseases. While the underlying principles governing diagnosis, treatment, and control are similar to those of temperate zones, there are considerable differences in the relative importance of these principles. For example, most of the tropical diseases depend on arthropod vectors for transmission; nonhuman reservoirs of infection exist in animals such as bats, armadillos, and crabs. It should be noted that a minimal knowledge of tropical medicine would raise the index of suspicion so that the physician would make early diagnosis of schistosomiasis, filariasis, kala-azar rather than allow long delays before the beginning of specific therapy and institution of preventive measures as happened in World War II. Even a few hours of instruction in our medical schools would go far in avoiding such happenings.

In addition to the assignment of physicians abroad for peacetime programs and the need for training in tropical diseases in case of national emergency, one is impressed with the increasing trade with tropical areas and the increasing amount of travel to and from these areas. These are some of the considerations that are giving a new importance to tropical diseases to physicians of the United States.

TONSILS AND ADENOIDS

To the Editor:—The symposium on the tonsil and adenoid question in THE JOURNAL, Feb. 13, 1954, is a boon to those of us who cope with this problem daily and who will profit by these expert opinions. The deformity of excessively high palates with resulting nasal obstruction, although not part of this subject, is such a common basic factor in hypertrophy of the tonsils that it should be mentioned as part of the problem. Primary disease of the tonsils is not common. Tonsil enlargement is often due to neutralizing lymphatic absorption of nasal infections promoted by obstructions. In children with an allergic tendency, particularly distressing complicating symptoms are not relieved by tonsillectomy. The advantage in including nasal obstructions in this discussion is that, whether the tonsils are removed or not, when such obstruction is present early application of orthodontia procedures often lowers the nasal floor enough to separate the septum from the turbinates and give relief of symptoms.

MISCELLANY

FEDERAL COMMUNICATIONS COMMISSION RULES REGULATING THE OPERATION OF MEDICAL DIATHERMY EQUIPMENT

In a public notice of Feb. 19, 1954, the Federal Communications Commission stated that a considerable number of medical diathermy machines that do not comply with its rules are still being used by doctors, or other persons, who either are not aware that they are violating the law or do not appreciate the compelling reasons that forced the commission to adopt its present rules governing the use of medical diathermy and other types of industrial, scientific, and medical equipment.

WHY IS IT NECESSARY TO COMPLY WITH THE COMMISSION'S RULES?

Some of the harmful effects that can result from diathermy machines that radiate excessively are indicated below:

National Defense.—It has been conclusively demonstrated that both planes and missiles can be guided to their targets by following radio signals. Because of that fact, the United States has instituted a comprehensive program known as CONELRAD (CONtrol of ELectro-magnetic RADiation), which is designed to minimize the usefulness to an enemy of radio signals originating in this country. A CONELRAD program for the control of radio broadcast stations during possible air raids is already in effect. Since planes can also utilize signals emanating from excessively radiating diathermy machines, it may be necessary to put such a program into effect with respect to such equipment, particularly if equipment of this type that radiates excessively remains in use.

Interference to Safety Radio Services.—Radio is of vital importance to safety. Radio is not only used for direct communication between planes and between air and ground but as a navigational aid, particularly when visibility is limited. Radiation from diathermy equipment on frequencies outside of the assigned bands is a potential hazard to both aeronautical communication circuits and to airplane landing systems. Among other important safety services are the Police Radio Service and the Fire Radio Service. In order to avoid serious accidents and the loss of life and property, it is essential that radiation from diathermy machines be confined to assigned bands or be adequately suppressed. That means that only equipment that complies with the commission's rules should be used.

Interference to Broadcast Reception.—One common type of interference from medical diathermy equipment concerns the reception of aural and television broadcast programs. Unfortunately, many doctors, as well as other users, apparently believe that this is the only interference that their diathermy equipment is capable of causing. For the benefit of operators of medical diathermy equipment, the commission has answered the following specific questions: "Why should I worry if I have received no complaints about my equipment?" The fact that a physician or other person has not received a complaint is not a guarantee that his diathermy machine is not causing objectionable interference, perhaps many miles away. The only practical way of knowing that diathermy equipment is not causing interference is through the use of type approval or certified equipment.

"If my equipment was legal before June 30, 1953, why is it dangerous now?" Medical diathermy equipment that radiates excessively has been an interference problem for a long time. The commission's rules initially became effective June 30, 1947; however, to enable the owners of existing equipment to amortize their investments, the commission gave the owners and users of equipment manufactured and assembled before July 1, 1947, a total of six years, until June 30, 1953, within which to comply.

"What should the owners and operators of noncomplying equipment do?" The owner or operator of a medical diathermy machine that does not comply with the commission's rules should do one of the following things: (a) Obtain a machine that has been type-approved by the commission and that bears a type approval number. A certificate of type approval means

that the commission's engineers have tested a prototype of the machine and have found that it complies with the requirements. Type approval is not an absolute guarantee that the machine will not cause interference, but it does indicate that, under normal conditions of installation and operation, the machine will not do so. (b) Have a competent engineer certify that the old type machine is capable of operating in accordance with the commission's rules. Such certification is accomplished in the manner specifically prescribed in the commission's rules; however, the owners of older diathermy machines are cautioned that the certification of such machines will usually require extensive modification or shielding by a skilled engineer, as well as the use of special field intensity testing equipment, and the rules also require that the certification must be renewed every three years. In many cases the certification process may prove more costly than the purchase of a new type-approved machine.

"How does the commission propose to enforce its rules?" It is hoped that when these facts are brought home to the users of illegal equipment, particularly those that relate to the dangers that may result from the use of such machines, the commission will receive a maximum degree of cooperation in the elimination of the illegal equipment; however, because of the serious potential dangers involved in the continued use of illegal equipment, the commission does not intend to rely solely on an educational campaign. It intends to use every means at its disposal to identify and eliminate the use of any equipment that does not comply with its rules.

The commission warned users of illegal equipment that the commission has available to it, and intends to follow, the following enforcement procedures wherever appropriate: (1) the issuance of cease and desist orders, enforceable in the courts, directed to the users of the illegal equipment; (2) application to the courts for injunctions against the use of illegal equipment; and (3) the institution in aggravated cases, of criminal proceedings against the operators of illegal equipment.

MILLIEQUIVALENTS

For many medical men who qualified more than a decade ago milliequivalents share some of the mystery that irrational numbers hold for the nonmathematical. But, simple units of measurement that they are, they have largely replaced such traditional though flexible units as milligrams per 100 ml. to record concentrations of ions. While readily convertible to metric units, their special features make them preferable for the estimation of the electrolytes of the plasma, which is becoming a commonplace laboratory investigation, essential for carrying out rational replacement or maintenance therapy of patients suffering from electrolyte depletion.

Milliequivalents are units of measurement no less than are the other, more familiar terms of metric weight; but they are units with this difference, that instead of being related arithmetically to other units of weight or volume within the metric system they imply a chemical relationship between the various ions under consideration. Thus, one milligram of sodium is not related to one milligram of potassium or one milligram of chloride except in so far as these amounts weigh the same, but one milliequivalent of sodium is chemically equivalent to one milliequivalent of potassium and to one milliequivalent of chloride and to one milliequivalent of bicarbonate, and in fact to one milliequivalent of any substance, although the actual weights of these amounts are not the same when expressed in milligrams. The equivalent weight of a substance is a chemical term defining that weight of the substance that will combine with or displace one gram-atom of hydrogen. A milliequivalent weight of a substance is its equivalent weight divided by 1,000, that is, the weight of the substance that will combine with or displace one milli-gram-atom of hydrogen. Adapting an old axiom, things that are equivalent to the same thing (in this case hydrogen) must be equivalent to one another, and it is this that justifies the use of the term milliequivalent in clinical chemistry today. Expressed in these terms, fluctuations in concentrations of electrolytes—not only in plasma but also in urine and gastrointestinal contents—come to have some meaning in relation to one another. Calculation of concentrations expressed in milliequivalents per liter from those in milligrams per 100 ml. is done by

multiplying the milligrams per 100 ml. by 10 to bring the concentration to milligrams per liter, and then dividing by the equivalent weight of the ion in question. The equivalent weight of the monovalent ions sodium, potassium, and chloride is equal to the atomic weight, namely, 23, 39, and 35.5 respectively. Some laboratories report the concentration of chloride in the form of sodium chloride, in which case the concentration in milligrams per 1,000 ml. must be divided by 58.5 and not by 35.5. Special factors have been calculated for the conversion of bicarbonate from volumes per cent and protein from grams per cent to milliequivalents per liter.

BUSINESS PRACTICE

The following material is based on a public relations manual issued by the Public Relations Department of the American Medical Association.—Ed.

THE PHYSICIAN AND HIS RECEPTION ROOM

Although many persons speak nostalgically of the "old family doctor"—the combination physician, father-confessor, and friend—few would entrust their care to him today, for often he had more sympathy than skill to offer. It is from fond memories of the horse-and-buggy doctor, however, that people draw their conception of the ideal physician. To the patient, a good physician is "gentle, kind, even-tempered, always available, tireless, inexhaustibly patient, everlastingly resourceful, and, up to this morning's radio broadcast, completely informed."

A good doctor-patient relationship, often termed "the most important factor in the practice of medicine," depends not only on giving people the best possible medical service but also in maintaining their confidence and friendship. Too often patients complain that doctors are cold and impersonal. The affection and friendship of the patient is won through giving him frank and friendly attention and relieving pain and easing the mind but, above all, by treating patients as persons. Patients want to feel they are important to the doctor as persons, not just as clinical cases. Says one physician, "Be glad to see patients, even if you are a little tired. Be frank; be prompt; and never give the impression that you are doing the patient a favor." Skill is no substitute for kindness. Cold, calculating science can never replace the warmth of a sympathetic personality. Healing the body is not enough. If a physician is to meet his medical responsibilities fully, he must comfort the soul, too. This is not the task of the psychiatrist alone. It is the plain duty of every practicing physician.

A patient may get his first impression of a physician as he enters the reception room. It is not necessary to hire an expensive decorator to redo the waiting room nor is it necessary to spend a great deal of money on furniture, carpeting, or drapes. The reception room should be decorated in cheerful harmonious colors, bright but not gaudy. A neat, comfortable, and attractive reception room shows patients that their doctor has their welfare at heart. In order to cut tensions produced by waiting to a minimum, the reception room should be tastefully and attractively decorated. The furniture should be comfortable and adequate for the peak number of patients to be accommodated each day. It should be arranged for reading or conversation. The room itself should be well ventilated and the temperature regulated for comfort. If possible, storage space for coats, hats, rubbers, and umbrellas should be provided. There should be an assortment of up-to-date magazines and light reading material, preferably in leather-bound covers to keep them from becoming prematurely dog-eared. The reading light should be adequate. Some physicians put up bulletin boards presenting information on health, education, and other interesting subjects. Others place writing desks in the reception room for patients' convenience or arrange a children's corner with small furniture and children's toys. Some physicians have found television helpful in keeping children occupied. Pictures, posters, plants, or cut flowers lend added charm to a reception room. A lighted aquarium or piped-in restful music may provide that extra touch that keeps patients loyal to their doctor.

BUREAU OF LEGAL MEDICINE AND LEGISLATION

MEDICOLEGAL ABSTRACTS

Expert Witnesses: Cross-Examination Relating to Fee Charged for Testifying.—This was an action for damages for injuries sustained by a passenger in a bus-truck collision. From an unsatisfactory judgment for the plaintiff in the trial court, the plaintiff appealed to the superior court of Pennsylvania.

The plaintiff recovered a verdict in the trial court, but it was too small. He appealed, contending that the meager verdict was the result of restrictions that the trial court placed on the cross-examination of one of the defendant expert medical witnesses.

Under cross-examination of the physician, the plaintiff developed the fact that the physician had testified in many cases over a long period of time, for the defendant company and others, although he skillfully evaded exact numbers, which he called "statistics." The physician testified that he had received \$50 for his pretrial examination of the plaintiff, and to the question, "What is your arrangement to be paid for testifying here?" he answered, "There are no arrangements made." He was then asked "How much do you expect to get paid for testifying here today?" The trial court sustained an objection to this testimony.

In a prior case the Supreme Court of Pennsylvania had said that it was pertinent for the jury to know what arrangements the doctors had made or were contemplating making for compensation for their services in the case and that the trial judge's refusal to require them to testify under oath and subject to cross-examination constituted a substantial error that made necessary the granting of a new trial. In the present case, to justify his ruling, the trial judge said: "A contemplated mutual arrangement and an *ex parte* expectation are very different things, for a man may expect more than he gets. If it be argued that the word 'expect' may be interpreted either as a mere hope or as reliance upon something certain but still in the future, it is our view that the latter meaning was eliminated by the doctor's statement that no arrangement had been made." On appeal, the judge said that apparently, under the opinion of the trial court, if the counsel had inquired concerning a contemplated arrangement instead of an expected arrangement his question would have been free from objection. The difference between the two words, said the court, is minute and vague. Both words describe "subjective mental processes"; both connote the mental state of looking forward; contemplation, as here employed, signifies a purpose in respect to the future; expectation is more than a bare hope, implying a high degree of certainty that a future event will occur. The prior Supreme Court decision, which used the expression "arrangements the doctors had made or were contemplating" clearly permits exploration of the future as well as of the past, of recompense that will be claimed as well as an express pre-trial agreement to pay a stipulated fee. Continuing, the court said, however, that the logic of words must yield to the logic of realities. In this case a physician with 32 years of experience as a court witness was testifying. His experience and prestige have undoubtedly created a demand for his services that he is able to sell in a seller's market. In all probability he is not obliged to negotiate for fees; he commands them; and serves only those who meet his terms. It would be in keeping with the practice of other professional witnesses if he indeed fixed his fees unilaterally and *ex parte*. Nevertheless, the witness, drawing upon his experience and his practice in charging and receiving fees, could have stated an estimate of the monetary value he placed upon his services; that is to say, what he expected to charge and receive and, even if he could not, the question itself was not outside of the "reasonable limits" of interrogation. The amount of an expert's fees, whether stipulated in advance of a trial or determinable in the future, has a direct and vital bearing upon his credibility, his interest, bias, or partisanship. Accordingly the judgment was reversed and a new trial awarded. *Reed v. Philadelphia Transportation Company*, 90 A. (2d) 371 (Pennsylvania, 1952).

Oxytetracycline and Chlortetracycline.—An analysis is presented of the clinical results obtained in 520 patients treated with either oxytetracycline (Terramycin) or chlortetracycline (Aureomycin) for a large variety of diseases, but chiefly for infections of the respiratory or urinary tract. Most of the patients were given oral doses of 250 mg. every four hours or every six hours, but 37 of them received 500 mg. doses at similar intervals. The incidence of toxic effects accompanying the different dosage regimens was noted, and special attention was paid to the occurrence of staphylococcal diarrhea. Favorable clinical and bacteriological results were obtained with each of the dosage regimens in patients with acute infections due to susceptible types of organisms. The results with each of the two antibiotics were, on the whole, fairly comparable, considering the relatively small number but wide variety of diseases treated and the number and character of the underlying complicating factors. No conclusions could be drawn with respect to the relative efficacy of the dosage regimens employed as compared with the larger doses that had been used previously. The most frequent toxic effects were those involving the gastrointestinal tract. The frequency of the occurrence of gastrointestinal complications, particularly of severe watery diarrhea, was significantly greater in the patients who were treated with oxytetracycline than in those who received chlortetracycline in the same dosage. With each of these antibiotics diarrhea was about twice as frequent among patients who received 250 mg. doses every four hours or 500 mg. doses every four or six hours than among those given 250 mg. every six hours. Fecal cultures were made for 38 of the patients in whom diarrhea developed during oxytetracycline therapy and for 22 of those in whom it developed during chlortetracycline therapy. Hemolytic coagulase-positive strains of *Micrococcus* (*Staphylococcus*) *aureus* were found as the only or predominant organism in the fecal cultures of 27 of the former and 4 of the latter. Diarrhea subsided fairly rapidly, and the normal flora returned

in the stools in most of the patients when the oral administration of the offending antibiotic was discontinued, and only general supportive measures were instituted promptly after the diarrhea began; this improvement occurred without relation to the subsequent use of other specific antibacterial agents or to the susceptibility of the fecal staphylococci to those agents.

Infections During Antimicrobial Therapy.—The authors present six case histories of patients in whom secondary infections developed during treatment with various antibiotics for primary infections. In each patient the relapse was caused by a micro-organism that was resistant to the particular drug used. Superinfections of this kind occur in a small but significant number of persons receiving antimicrobial therapy. There are three basic types of mechanisms by which superinfection can result. 1. The drug may so alter the natural bacterial flora of the body that insensitive microbes become numerically predominant. If these initially scarce micro-organisms have the ability to invade the blood stream or specific tissues, a new infection may result. 2. The drug may actually stimulate bacterial growth, according to the Arndt-Schulz law that poisons in small doses are stimulants. This phenomenon has been demonstrated in vitro with penicillin. Garrod has shown that there are appropriate stimulating concentrations of penicillin for both sensitive and resistant species of bacteria. 3. The drug may bring about an alteration of certain tissues, as in clinical vitamin deficiency states, diarrhea with enterocolitis, and, reportedly, pseudomembranous enterocolitis.

Artificial Kidney in Chronic Renal Disease.—The artificial kidney is an important auxiliary in the treatment of chronic renal insufficiency. The four main indications for its use are (a) to obtain prolonged remissions in selected symptomatic patients, (b) to prepare patients for indicated surgical procedures, (c) to maintain patients in whom the delicate state of equilibrium in renal function is temporarily upset, and (d) to delay the progress of physiological abnormalities and the advent of more pronounced symptoms in relatively asymptomatic patients; more experience is needed to settle this last point. The factors that appear to predispose to a prolonged remission are (a) a general symptomatologic and chemical "plateau"; (b) the absence of severe generalized vascular disease, even though hypertension is present; (c) the absence of overwhelming infection or septicemia; (d) polyuria, and (e) a predialysis serum sodium level above 130 mEq. per liter. Favorable chemical responses were noted after 20 dialyses in 15 patients who had far advanced renal insufficiency of varying cause. After all 18 dialyses in which evaluation was feasible, the symptomatologic response was favorable. Short remissions occurred after 13 dialyses and long-term ones after 7 dialyses. The average duration of the short remissions was slightly longer than 3 days; the average duration of life after the 13 dialyses was 21 days. The longest of the long-term remissions was 104 days. One of these remissions lasted only 20 days, at which time death caused by myocardial infarction and peritonitis occurred; at the time of death symptoms associated with uremia had not reappeared. Although many patients with chronic renal insufficiency have been treated with the artificial kidney, more must be observed before any definite conclusions can be reached. It is emphasized that the series presented consisted mostly of patients in the terminal stages of their disease.

Hydralazine (Apresoline) Hydrochloride in Treatment of Hypertension.—The results obtained by giving only hydralazine (Apresoline) hydrochloride to one group of ambulatory patients with hypertension were compared with those obtained by giving placebos of similar appearance to another group. The alternate patient method was used in determining the distribution of the drug and the placebo. All patients were seen by the same observer at each clinic visit, and all were apparently benefited by the regular visits to the same physician. Some lowering of the blood pressure was found in each group, but the decline in the patients receiving hydralazine was statistically more significant than that found in those given the placebos. Patients vary greatly in their response to hydralazine; of the 37 receiving the drug, 12 had a drop in diastolic pressure of 20% or more (either while supine or sitting), some showed no change, and in 2 the diastolic pressure increased. Side-effects, chief among which was an occipital headache, were common, and they were severe enough to necessitate discontinuance of the drug in 11 patients. Two of the 28 patients receiving placebos discontinued them because of headache and nausea that they felt were drug-induced. A drop of more than 20% in the diastolic pressure, while sitting, was found in only one of the patients in the placebo group. Comparison of the figures obtained in patients who have been receiving either hydralazine or the placebo for more than six months shows that the significant difference between the two groups is persistent, indicating that the drug is effective even after long-continued use. The response of the individual patient, however,

cannot be predicted. Three hospitalized patients with nitrogen retention, who were among several treated with hydralazine but not included in the study groups, appeared to be adversely affected, suggesting that hydralazine should not be given to patients with uremia.

Effects of Cinchona Alkaloids.—The long-term effect of cinchona alkaloids on the blood pressure was studied by giving quinidine sulfate, quinine sulfate, and a lactose placebo, dispensed in identical capsules identifiable only by code number, to 44 patients with long-standing hypertension. The double blind principle was used throughout the study so that neither the patient nor the attending physician knew which substance was being given at any particular time. The patients were told that the test materials were "medicine for the blood pressure" and were instructed to take three capsules a day, one before each meal. Each capsule contained 0.3 gm. of a drug, and this dosage (0.9 gm. per day) was considered to be the maximum amount of alkaloids that could be taken regularly by an unselected group of patients. Undesirable side-effects were common even with this dosage, and many patients were unable to tolerate it, especially when quinine was being given. The patients, divided into two random groups at the first visit, received courses lasting four weeks of quinidine sulfate and placebo in alternate order. At least two weeks of observation without therapy followed, and then the patients, redivided into two groups at random, were given quinine sulfate and placebo alternately in courses lasting four weeks, as before. Statistical analyses alone do not permit accurate evaluation of drug therapy in hypertension, because treatment in itself frequently produces a marked reduction in the blood pressure even of stabilized hypertensive patients. The double blind method, however, was apparently successful in controlling the nonspecific effects of therapy. Summaries of the data obtained, prepared by one who had no contact with the patients, showed that the beneficial effects apparently produced by the cinchona alkaloids on the blood pressure and symptoms of these patients were equalled in each case by those of the lactose placebo. Subjective factors proved unreliable as guides to the result of treatment; both the patients and the attending physicians expressed opinions at variance with the condition of the pressure and with each other. Hypertensive symptoms, in fact, seem to have little, if any, connection with hypertension itself.

Fibrous Adhesive Pericarditis Following Corticotropin Therapy for Rheumatic Pancarditis.—Sheely presents the case of a 10-year-old girl in whom acute rheumatic pancarditis developed after an attack of acute tonsillitis. Treatment with adequate amounts of corticotropin was followed by the development of an intractable congestive state characterized by hepatomegaly, recurrent tense ascites, and dependent edema. This congestive state typical of Pick's syndrome occurred approximately two months after institution of therapy with 800 mg. of corticotropin, at a time the patient was clinically improved, with great improvement in appetite, sense of well-being, and subsidence of toxicity. At no time during the 17 months of hospitalization was fluid in the pleural spaces or persistent clinical signs of pulmonary congestion detected in repeated physical examinations and roentgenographic studies. In the

absence of a presystolic murmur, it was the clinical impression that the patient had constricting pericarditis with resultant enlargement of the right side of the heart and portal hypertension. Necropsy revealed a dense fibrous adhesive pericarditis; there was no true mitral stenosis. This condition produced the clinical picture of a constrictive pericarditis. Although the use of corticotropin cannot be definitely linked to the pathological lesions in this case, the occurrence of Pick's syndrome two months after steroid therapy leads to interesting considerations in the light of recent observations on the effect of these steroids in other vascular conditions. Shick and others recently observed, in pathologically proved cases of periarteritis nodosa treated with corticotropin and cortisone, that massive fibrosis resulted in the involved arterioles and medium-sized arteries extensive enough to obliterate these vessels, producing infarctions in the involved visceral organs.

Hyperglobulinemia as Cause of Hemophilia-Like Disease.—Nilsson and Wenckert of Malmö, Sweden, call attention to the fact that in recent years several cases of a formerly unrecognized coagulation defect have been described. This defect is characterized by a hemophilia-like hemorrhagic state and caused by the presence in blood of a circulating anticoagulant that is active in the first phase of coagulation and that is neither heparin nor anticephalin. The first case was reported in 1940 by Lozner, Joliffe, and Taylor. Thereafter, more than 20 similar cases have been described. In 1950 the term "Hemm-körper" (inhibiting body) hemophilia was applied by an Austrian investigator. Other workers reported the presence of circulating anticoagulants antagonistic to thromboplastin or to the formation of thromboplastin in patients with true hemophilia following multiple transfusions. No clear-cut distinction can be made between these two groups. The first group comprises only genuine hemophiliacs, that is, only men, while the second includes both men and women. The authors present a case of probably familial hyperglobulinemia. A 44-year-old woman had a circulating anticoagulant, antagonistic to the initial phase of the coagulation, most likely to the antihemophilic globulin. The anticoagulant factor was separated by means of salt precipitation and by electrophoresis. It was shown to be identical with one of the patient's abnormal gamma globulin. There is no reason to suppose an isoimmunization process. The coagulation defect is, therefore, assumed to be a secondary phenomenon to the patient's probably familial protein disturbance. Dysproteinemia has been observed in hemophilia-like diseases several

times, but the etiological connection between the coagulation anomaly and the protein disease has not been previously established. On the other hand, even serious dysproteinemias seem rarely to be complicated by a circulating anticoagulant. A connection between the sedimentation rate and the coagulation of the blood was shown to be present in this patient.

Control of Hypertension by Hyphex.—Hyphex, a mode of therapy in which hydralazine (Apresoline) is combined with hexamethonium chloride, was used for 6 to 25 months in the treatment of 258 patients with hypertension. Untoward reactions are reported. Minor unwanted effects of hexamethonium chloride, which produces a partial blockade of all autonomic ganglions consisted of orthostatic hypotension and suppression of intestinal motility with resulting constipation; blurring of vision, which occurred frequently; dryness of mouth and hypotonicity of the bladder, which were common; decreased potency or impotence in men, which was constant in the early stage but complete or partial recovery was noted in many; and cold intolerance, which was frequently observed. Minor reactions to hydralazine consisted of stuffy nose, periorbital edema, lacrimation, headache, generalized aching, and prostration in most of the patients on initiation of therapy, but these varied greatly in severity. All of these symptoms were milder and of shorter duration when hydralazine was used in combination with hexamethonium chloride, than when hydralazine was used alone. Fatal complications were observed in the form of interstitial pneumonia in five patients, uncontrolled hypotension in one, and sudden death in one. Hydralazine apparently caused arthritis and "collagen-like" disease in 16 patients and repeated febrile responses in 6. Serious obstructive phenomena caused by hexamethonium chloride in previous organic obstruction occurred in 10 patients. Of the 44 patients (17%) with untoward reactions, 8 (3%) died, 5 of interstitial pneumonia, 1 of pneumonia after parotitis, and 2 from simultaneous administration of both drugs. Despite untoward reactions and undesirable side-effects, the combined use of hydralazine and hexamethonium chloride is an effective and practical method of treating severe hypertension provided precautions are taken to minimize serious consequences, for the benefits observed clearly have outweighed the risks. Neither agent is ideal.

Treatment of Shock Accompanying Myocardial Infarction.—Of 14 patients who were between the ages of 39 and 70 and who were in severe shock accompanying myocardial infarction, 7 were treated with intravenous infusions of phenylephrine (Neo-Synephrine) hydrochloride and the others received intravenous infusions of levarterenol (Levophed). The latter was administered in a solution containing 4 mg. of levarterenol and 5% dextrose in each liter of distilled water. Phenyl-

ephreⁿ was administered in a concentration of 10 mg. per liter in two patients and 20 mg. per liter in the others. The rate of infusion flow was determined by the level of systolic blood pressure that was maintained below 120 mm. Hg in each patient except one, a known hypertensive with a blood pressure of 134/90. The rate of infusion flow ranged from 5 to 100 drops per minute. If the blood pressure remained stable with the slower flow rate, the pressor amine administration was discontinued. If shock occurred, the infusion was restarted. Twelve of the 14 patients were in congestive heart failure. Six patients in congestive heart failure treated with levarterenol recovered. Five patients in congestive heart failure treated with phenylephrine responded with an immediate rise of blood pressure, but the pressure failed to stabilize and the patients succumbed despite continuous infusions of phenylephrine. Two patients with no evidence of congestive heart failure were brought out of shock by phenylephrine. One of these patients recovered; the other died 48 hours after the phenylephrine infusion was discontinued. One patient treated with both sympathomimetic amines failed to respond to phenylephrine and was later brought out of shock by levarterenol. This patient died 18 hours after discontinuance of levarterenol therapy. Determinations of relative contractile force and arterial pressure changes were carried out after 51 intravenous injections of *l*-epinephrine, levarterenol and phenylephrine in unanesthetized dogs. Results showed, that levarterenol produced pronounced increments in heart contractile force, in addition to pressor effects in the experimental animals. The contractile force increments were of similar magnitude to those produced by *l*-epinephrine. Phenylephrine was observed to be more predominantly a pressor amine, producing only minimal changes in heart contractile force. The effect on contractile force of the heart of levarterenol is presented as a basis for the high recovery rate observed with this amine in the treatment of shock accompanying myocardial infarction, particularly in patients with associated congestive heart failure.

Scrotal Diverticulum of Urinary Bladder.—The case presented by Vallett was that of a man, aged 68, who was hospitalized with the chief complaint of not being able to void. He had difficulty in passing urine for 10 years. There was a doughy mass in the right scrotal sac. Rectal examination revealed benign overgrowth of the prostate. An excretory urogram showed prompt appearance of the dye in both kidneys. A 60 minute film showed the bladder incompletely filled and irregular in outline on its right lateral aspect. This suggested some factor responsible for drawing the bladder to the right. Tumor was thought of, but in a lesion of this extent there would have been a history of hematuria. Both ureters in their lower one-third were displaced to the right. Cystoscopy revealed a normal bladder mucosa, but the mucosal surface of that part of the bladder wall that appeared displaced to the right in the excretory films could not be seen. It was assumed that this was a local sacculated area consequent to bladder neck obstruction. A diagnosis of benign overgrowth of prostate and right hydrocele was made and an operation planned to resect the hydrocele, and this was to be followed by electric endoscopic vesical neck resection. The right scrotal sac was opened, and it became apparent that there was no hydrocele. A mass was seen that was doughy and compressible. Careful dissection of

the mass revealed bladder muscle, and an incision into the lumen showed a bladder diverticulum. There was no urine in the diverticulum. A finger could be passed through the neck of this structure into the bladder proper. A transverse suprapubic incision was made and the bladder opened. It was now possible to invert the diverticulum and push it up through the external ring on into the bladder proper. However, it was apparent that diverticulectomy could be carried out more easily from the scrotal area. Consequently, the diverticulum was returned to this area and resected, purse-stringing its neck, which in turn was pulled up through the external inguinal ring, inverted, and tied from within the bladder. The prostate was left for subsequent endoscopic vesical neck resection that was carried out 18 days later. Diverticulum of the bladder in the scrotum is rare. The author makes a plea for the routine employment of the cystogram in urologic examination. The information gained is often greater than that derived from cystoscopy. It is the only accurate method of demonstrating scrotal cystocoele.

Viomycin Sulfate in Tuberculosis.—Five patients with advanced pulmonary tuberculosis and without history of previous antimicrobial therapy were treated with 3 gm. of viomycin sulfate daily for 13 weeks. The drug had a definite antimicrobial effect, but was too toxic for widespread use in tuberculosis therapy. Thirty-five patients with pulmonary tuberculosis were given 2 gm. of viomycin sulfate twice weekly and 12 gm. of *p*-aminosalicylic acid daily, and 24 control patients with pulmonary tuberculosis were given 2 gm. of dihydrostreptomycin twice weekly and 12 gm. of *p*-aminosalicylic acid daily. Viomycin sulfate in doses of 2 gm. twice weekly combined with 12 gm. of *p*-aminosalicylic acid daily was of slight toxicity. Tinnitus may be expected to occur. Allergic symptoms were not a major problem. Auditory nerve damage of a serious degree was not frequent. Streptomycin-resistant organisms were affected by viomycin, and patients having such organisms improved under intermittent viomycin treatment. Bacterial resistance to viomycin did not develop to a significant degree among patients treated for six months. Clinical improvement and clearing of exudative lesions evident roentgenologically were more striking in the patients treated with dihydrostreptomycin combined with *p*-aminosalicylic acid; however, the effectiveness of viomycin combined with *p*-aminosalicylic acid was definite and demonstrable. The clinical use of viomycin is feasible in the presence of streptomycin-resistant organisms and allergic sensitivity to streptomycin. Its use with newer antimicrobials should be explored.

Death from Carcinoma of the Lung.—Boyce analyzes 186 fatal cases of carcinoma of the lung from the Charity Hospital of Louisiana at New Orleans. Of the 186 patients, 33 underwent pneumonectomy and 22 of these died during the immediate postoperative period. Eleven others, who survived the operation, died later in the hospital. Only 4 of the 11 lived for two years or more, and only 1 lived as long as five years. Twenty-six of the 33 fatal pneumonectomies were palliative; this means

that the risk was greater in them than it would have been in curative operations. In 20 nonsurgical cases, in which the duration of symptoms before medical consultation was a month or less, 2 patients lived for a year after they became clinically ill, but 2 others lived for only two weeks, 3 for less than a month, and 5 for less than two months. These fatalities illustrate the unhappy and paradoxical fact that the shorter the duration of symptoms, the shorter also is the duration of life after their onset. The correlation between brevity of symptoms and the total illness was also clear in many of the 23 patients who submitted to surgical exploration, but the duration of life in this group was slightly longer than in the nonsurgical group. The extraordinarily wide extent and rapid development of extension and metastases in carcinoma of the lung was illustrated by 21 cases of metastases to the liver, 18 to the brain, 16 to the bones, 13 each to the adrenal glands and the heart and pericardium, 12 to the cervical lymph nodes, 11 to the aorta, 7 to the superior vena cava, 6 to the supraclavicular lymph nodes, 4 to the kidneys, 3 to the pancreas, and 2 each to the intestines and the thyroid. Only when pneumonectomy can be carried out promptly in respect to pathological process, not symptoms, are the results of treatment rewarding, but few patients were operated on promptly because they often delayed seeking treatment. Physicians whom they first consulted and hospital staff members often failed to suspect the diagnosis or were slow to recommend surgery. The investigation was sometimes perfunctory, sometimes unnecessarily repetitious, and sometimes enmeshed in hospital routine and protocol. Appallingly often the clinical course was far too brief to permit any positive action. If the mortality is to be lowered in carcinoma of the lung, which is now of major importance among malignant diseases, the profession must (1) develop a far higher index of suspicion concerning it; (2) explore the chest on suspicion much oftener; (3) stress the urgency of diagnosis and treatment; (4) investigate the whole person rather than limited fields whenever adults seek medical care for any reason whatsoever; and (5) make the fullest possible use of data available in mass chest surveys.

Painful Elbow.—An insidious condition of the elbow, which is found with relative frequency in heavy industry, is epicondylitis. This is a periostitis of the bone, affecting either the median or lateral epicondyle of the humerus, usually with some concomitant involvement of the nerves surrounding the area—the median, the radial, and/or the ulnar. The radiohumeral ligaments and even the bursas may be involved. It is the result of repeated bruising of the elbow. It causes moderate pain, and at the beginning even exquisite tenderness. Motion of the arm and forearm may be limited, but it is not definitely restricted. The pain shoots up and down the arm and forearm from the lateral or median epicondyle and

usually is intensified by grasping or lifting with the extended forearm. The condition is chronic and largely refractory to treatment, but with the passage of time, it regresses spontaneously. During the last two years, the author diagnosed 20 cases, 3 of which are presented. Numerous treatments all proved to be of temporary value or just a means of tiding over during the acute stage. There is loss of efficiency but no disability. The Workmen's Compensation Commission's final opinion was always discomfort over the elbow region, no disability.

BCG in Prophylaxis of Leprosy.—De Souza Campos orients his note toward three questions asked by Fernandez in 1951.

1. What is the value of the positive Mitsuda reactivity induced by BCG in a healthy person? 2. What is the incidence of leprosy among persons vaccinated with BCG and among those not so vaccinated? 3. Are there well-substantiated cases of lepromatous leprosy developing in persons previously vaccinated with BCG? From the small number of statistics that exist, the following conclusions can be drawn. BCG vaccination clearly has a protective effect against leprosy infection, as shown by the incidence of only 0.6% among the vaccinated persons as against 5.6% among the nonvaccinated ones during the same period of time. Among the vaccinated contacts, only tuberculoid leprosy developed, reactional in five, the childhood nodular form in four, and circinate in one. In contrast, of the cases among the nonvaccinated contacts 26.3% were of the lepromatous form, 46.9% of the undifferentiated form, and only 26.8% of the tuberculoid form. These data are obviously initial ones, and subsequent observations may alter them quantitatively and qualitatively. There is no doubt in the author's mind, however, that they indicate clearly that BCG has a protective effect against leprosy infection.

Lepromin Reaction in Diagnosis.—Although the international classification of leprosy is based on clinical, bacteriological, histological, and immunological criteria, the author feels that the immunological one as revealed by the late reaction to the lepromin test (Mitsuda phenomenon) is the most important and dependable one because it is the least subject to change. In the prolonged evolution of the disease, the clinical, bacteriological, and histological elements not only undergo modification but may eventually disappear entirely, whereas the immunological one remains, as a rule, constant, positive in the tuberculoid form and negative in the lepromatous form. With respect to the indeterminate group, the author has never seen a strongly positive case change to negative or evolve to the lepromatous form. On the other hand, cases with negative lepromin reactions, especially those that have positive bacteriological evidence and that are insufficiently treated, usually change to the lepromatous form. The number of cases observed is, however, relatively small, and, to permit definite conclusions to be drawn, indeterminate cases should be studied thoroughly at other centers and immunological curves should be established by testing every three months to demonstrate immunological evolution. If it is proved that the cases with negative lepromin reactions do eventually become the lepromatous form, they should be regarded as prelepromatous or potentially lepromatous. The lepromin reaction assumes its full value in classification in the cases without skin lesions, since guidance from clinical, bacteriological, or histological aspects is lacking. Where the Mitsuda reaction is frankly negative, it may be concluded that the disease is of the lepromatous form with nerve localization, if the patient has never had skin lesions or a neural form secondary to a previously lepromatous

one in which there were skin lesions that have disappeared. When the reaction is frankly positive the disease can generally be regarded as tuberculoid leprosy of the nerve where there have never been skin lesions or neural, secondary to previously tuberculoid leprosy, when skin lesions have disappeared. Two cases are reported to illustrate how the immunological findings alone permitted diagnosis of the clinical form; these diagnoses were confirmed by biopsy of the cubital nerve.

Propylthiouracil in Graves' Disease.—Propylthiouracil was given to 60 patients with Graves' disease who had small to moderate-sized diffuse goiters and hyperthyroidism. All patients were followed from four to six years after treatment with propylthiouracil was discontinued. In 40 (66.7%) of the 60 patients thyrotoxicosis was in remission at least four years after the drug was discontinued. The remaining 20 patients (33.3%) had relapses, and in 13 of them a relapse occurred within five months after treatment was discontinued. Remission implies complete freedom from symptoms and signs of hyperthyroidism and a basal metabolic rate lower than $+10\%$. In 32 of the 40 patients (80%) who had lasting remissions, the hyperthyroidism was completely controlled within three months after treatment was started. In most patients, a dose of 200 mg. of propylthiouracil per day given as four 50 mg. tablets (one after each meal and one at bed time) was adequate for complete control of the hyperthyroidism. Because of occasional slow response, the amount of the drug was increased to 300 or 400 mg. per day if necessary. It is the authors' impression that the longer treatment is continued the more likely is the chance of lasting freedom from the thyrotoxicosis, but, in 8 of the 40 patients in whom the disease remained in remission, treatment was stopped five months or less after control was first obtained.

Histopathological Lesions in Thyroid After Radioiodine Therapy.—The hyperplastic or nodular thyroid glands of 23 hyperthyroid patients were irradiated with radioactive iodine (I^{131}) and examined microscopically. The patients treated toward the end of the study received 120 μ c of I^{131} per estimated gram of thyroid tissue, while earlier in the study small doses of I^{131} were employed. The total dose of I^{131} administered varied from 471 to 23,439 μ c. At the time of thyroidectomy, 21 patients were euthyroid and in most of them the thyroid gland had decreased in size. Of the remaining two patients, one died from diabetic acidosis and the other from laryngeal

spasm during thiopental (Pentothal) sodium administration because of a manic state; both of these patients were still hyperthyroid. On microscopic examination thyroid glands of seven patients were predominantly hyperplastic and no definite radiation effects were observed. The thyroid glands of nine patients had lesions identical with those of Hashimoto thyroiditis. This high incidence of thyroiditis, when compared with that in nonirradiated hyperplastic thyroids, is highly significant statistically. This suggests that Hashimoto thyroiditis is one effect of internal irradiation with radioiodine. Four thyroid glands contained multiple nodules and showed moderate follicular atrophy of the residual glandular tissue. It was concluded that this atrophy was also the result of injury by irradiation. Three thyroids showed diffuse follicular atrophy and fibrosis, regarded as classic lesions caused by irradiation. Vascular disease in the 23 thyroid glands was minimal and had no relation to the regressive thyroid lesions observed. Pleomorphic and hyperchromatic alterations of thyroid epithelial cells observed in these thyroids were not believed to be related directly to irradiation. These studies indicated that amelioration of hyperthyroidism may occur after irradiation of the thyroid gland with I^{131} , usually in the absence of the classic structural changes generally associated with injury from irradiation.

Occlusion of Mesenteric Artery.—Acute occlusion of the superior mesenteric artery is reported in a 64-year-old man and in a 67-year-old woman. The occlusion was correctly diagnosed in both patients, and surgical removal of an obstructing intra-arterial plug was carried out successfully, although both

patients died within 60 and 56 hours, respectively, after the operation. Death of the man resulted from myocardial failure, and the woman died of massive intraperitoneal hemorrhage from mesenteric veins that had been cut in the dissection necessary to expose the superior mesenteric artery in the course of the operation. Necropsy in both cases revealed that the bowel was normal and in a condition consistent with survival. In the man the bowel had been totally deprived of blood for 14 hours and in the woman for 12 hours. In both patients, the superior mesenteric artery and its branches remained patent after removal of the obstructing lesion. The author makes several conclusions. 1. Circulation in the superior mesenteric artery and its branches can be restored by removal of the obstructing thrombus. 2. Circulation within the bowel wall compatible with continuing viability can be assured by this procedure. 3. The bowel wall can survive total deprivation of blood for a period of 14 hours. Nothing can be said with reference to survival beyond this time limit, but parallel experience with muscle tissue generally would indicate that it cannot safely be exceeded. 4. During the operation, particular care should be taken to secure arrest of hemorrhage, which may occur after restoration of the mesenteric blood flow. This applies particularly to the dissection of mesenteric fat that is necessary to expose the superior mesenteric artery. 5. The postoperative use of heparin should be avoided. Sufficient reliance can be placed on flow velocity in an artery to prevent reformation of a thrombus at the site of the incision into the vessel.

Débridement with Papain.—The fibrinolytic enzyme papain, the dried milky juice of the melon tree *Carica papaya*, was given a therapeutic trial in the débridement of chronic suppurative and necrotic areas of 13 children and 7 adults with second and third degree burns, chronic leg ulcers, gangrene, carbuncle, chronic suppuration, and dry crusts. Several commercial preparations of papain were used that varied greatly in potency. In three patients, the fibrinolytic potency of the enzyme was compared with that of a standard preparation of streptokinase-streptodornase and was observed to be similar. Two methods were employed for the treatment: (1) direct application of the powder with a common vaginal insufflator, and (2) application of wet dressings with freshly prepared solutions of the enzyme, ranging from 2 to 5%. Both methods proved effective provided that the lesion and the dressings were prevented from drying within a minimum period of 24 hours by using several layers of surgical gauze well soaked with isotonic sodium chloride solution and a final layer of petrolatum gauze. Papain did not cause any deleterious action on healthy tissues, and systemic or generalized reactions were not noticed during its application. The powder and solutions used were not bacteriologically sterile and, nevertheless, no reaction attributable to their application was observed. The cost of papain is so low that any hospital or patient can afford to use it extensively.

Subendocardial Fibroelastosis.—The infant whose case is reported had been born at term, but the mother had had a moderate toxemia of pregnancy. Physical examination at birth and subsequent neonatal course suggested that the child was normal. The infant was seen again at 3 months of age because of anorexia and irritability. Examination showed anemia. There was a good clinical response to administration of iron, liver, and vitamin B₁₂. One week prior to admission the patient seemed to have a "cold" with nasal discharge, cough, and return of anorexia and irritability. Rapid, irregular respirations were noted, and the infant refused food and seemed to cry continually. The respirations were rapid and grunting in type. The cyanosis became worse on crying. There was lack of breath sounds with an impaired resonance over the left chest. The heart sounds were indistinct. The infant was pneumonia with atelectasis and pleural effusion in the left lung. The patient was placed in oxygen and given penicillin and streptomycin parenterally. By the second hospital day, there was no improvement in respiration, but cyanosis was no longer present and pneumonia seemed unlikely. On the third day, antibiotics were discontinued. The infant became more distressed without oxygen and gave indications of being in severe pain. A diagnosis of subendocardial fibroelastosis was considered as well as a possible anomalous origin of the left coronary artery. On the fifth hospital day the condition was worse, and congenital heart disease was thought of. On the ninth day signs of decompensation developed and digitalis was started. A pericardial tap was done to relieve possible tamponade but no fluid was found. The patient exhibited a brief period of Cheyne-Stokes respirations and died on the 13th hospital day. Autopsy revealed dilation of the right auricle. The heart weighed 88 gm. On microscopic examination, sections of the interventricular septum showed endocardial thickening due to proliferation of loose, basophilic tissue. Toward the myocardium, this tissue became progressively more dense and collagenous. The lungs showed atelectasis. Two types of endocardial thickening may be recognized: primary and secondary. The latter is a reparative fibrosis and may be found in such diseases as myocardial infarction, rheumatic fever, diphtheria, subacute bacterial endocarditis, malignant nephrosclerosis, periarteritis nodosa, disseminated lupus erythematosus, and beriberi. The primary type may be found at any age but it is commoner in infants and children. The symptoms in the reported case were similar to those of previous reports, but cardiac pain seemed severer. In children this disease is best explained as a developmental anomaly, perhaps an overgrowth of the endocardium of the left bulbous cordis. It may also be secondary to a valvular or other cardiac defect leading to anoxia of the endocardium. In adults, the etiology and pathogenesis remain obscure. Rapid myocardial failure in a previously healthy person, with or without peripheral embolization, should suggest this disorder.

Treatment of Pediculosis Ciliarum in Infants.—According to Ronchese pediculosis (infestation with Phthirus pubis or crab lice) of the eyelashes and the edges of the eyelids is rare in adults but less rare in infants, who become infested by passage of the lice from the axillary or chest hair of the parents or attendants. The lice are visible to the naked eye or can be seen with the help of magnifying glasses. Treatment is simple; the lice and ova (nits) are easily picked out with a pair of cilia forceps (tweezers) or trachoma forceps (not just any forceps). The removal of the nits is facilitated by the infant's tears. In cases of such long standing that acute or chronic blepharitis has developed, antiseptic or antibiotic medication may be indicated. In early uncomplicated cases removal of the lice and nits is sufficient and medicaments are unnecessary. Recurrences are due to reinfestations from the same source, parents or attendants.

Hemorrhage from Gastroesophageal Lacerations.—Decker and his associates say that since the original descriptions of gastrointestinal hemorrhage caused by cardioesophageal lacerations induced by vomiting presented by Mallory and Weiss more than twenty years ago, there have been no further reports of this syndrome. Several large series of gastrointestinal bleeding recently studied from a clinical standpoint make no mention of this syndrome as a cause for hematemesis. However, among 101 patients with gastrointestinal bleeding, recently examined at autopsy at the laboratory with which these authors

are connected, 3 were found in whom death was caused by cardioesophageal lacerations. At least 11 cases of gastrointestinal hemorrhage due to cardioesophageal lacerations have been examined at autopsy in their laboratory. Clinical and pathological observations in these cases and six case histories illustrative of various features of the syndrome are reported. Examination of the case histories, in an attempt to clarify the pathogenesis of these lesions, revealed that the common factor was vomiting. Analysis of the cases yielded no explanations more reasonable than that advanced by Mallory and Weiss—namely, that the lacerations were produced by violent retching movements, which forced the gastric contents against a contracted cardiac sphincter. Reports of cases of spontaneous rupture of the esophagus emphasize the importance of violent retching and vomiting. The similarity of these conditions suggests a common mechanism. Atrophic gastritis is a possible underlying factor in the production of lacerations at the cardia. Atrophic mucosa may be less resistant than normal mucosa to the traumatic effects of vomiting. A significant degree of atrophic gastritis was present in six of the eight cases in which specimens of gastric mucosa were available for microscopic study. In animals, gastritis with ulceration and bleeding can be produced by a variety of nutritional deficiencies, particularly of components of the vitamin B complex. Alcoholism is commonly accompanied by vitamin deficiencies, particularly of the C and the B group. Most of the cases of this syndrome originally reported by Mallory and Weiss were associated with alcoholism. Many of the cases in the present series, however, were associated with a variety of diseases not only in the gastrointestinal tract but also in remote organs. Protracted vomiting or retching remains the common etiologic factor in all cases. Associated pathogenetic factors include chronic atrophic gastritis, alcoholism and nutritional cirrhosis.

Peripheral Vascular Collapse After Subcutaneous Use of Hypertonic Nonelectrolyte Solution.—Butler presents a case in which 1,200 cc. of hypertonic nonelectrolyte solution was given subcutaneously on the second day of an uneventful post-operative period. Severe peripheral collapse resulted. The patient responded well to administration of plasma and whole blood. The author cites experimental observations and a warning editorial on the peripheral vascular collapse that may be induced when hypertonic nonelectrolyte solutions are injected subcutaneously. The collapse can probably be explained by the shift of fluid and electrolytes from one body compartment to another. Subcutaneous infusions should probably be restricted to the use of isotonic electrolyte solutions.

Mitral Commissurotomy.—As a result of their experiences with 100 patients operated on for mitral stenosis, Antonius and co-workers subscribe to a compromise view between the extreme recommendations of two surgical schools that consider for mitral commissurotomy those patients with dynamically significant mitral stenosis in whom early symptoms have appeared and progressive congestive heart failure has not developed. Contraindications to surgical intervention consist of active rheumatic infection, subacute bacterial endocarditis, significant aortic valvular lesions, pronounced mitral insufficiency, pronounced cardiomegaly with extensive myocardial damage, emotional instability, intractable heart failure, or associated hypertensive or coronary heart disease. History and physical examination, fluoroscopy, electrocardiography, and cardiac catheterization may be utilized in arriving at the conclusion regarding suitability for surgical intervention. The underlying physiology of mitral stenosis determining the rationale for

such surgical intervention is outlined. Surgical repair of the deformed valve is but an adjunct in the care of rheumatic cardiac patients; they may be restored to great activity, enjoying a more normal life, yet they must, for the immediate future, be considered as cardiac patients under the continued supervision of their physicians.

Iatrogenic Meningitis.—Two cases of meningitis resulting from lumbar puncture for spinal anesthesia, one in a 19-year-old woman and one in a 60-year-old man, are reported with an extensive review of the literature. Iatrogenic meningitis is increasing. Lumbar puncture for diagnosis, anesthesia, or therapy is responsible for most cases. Routes of bacterial contamination are the anesthetic solution, unsterile instruments, supposedly sterile water used in rinsing syringes and needles, "sterile jars" used in storing syringes, air, and vials of penicillin used for intrathecal medication. Culture of the spinal fluid of both of the authors' patients revealed *Pseudomonas aeruginosa*, the causative agent in most cases of iatrogenic meningitis. Examination of the spinal fluid with ultraviolet light is a simple, rapid clinical means of identifying this organism. The diagnosis of iatrogenic meningitis is usually simple to make. A history of lumbar puncture followed in 12 hours to 10 days by meningitic signs establishes the diagnosis. This type of meningitis, in contrast to the epidemic meningococcal type, tends to be subacute only in its intensity; the natural course of the disease is long and is characterized by remissions and relapses. Exacerbations may occur even months after an apparent cure. Penicillin not only was ineffective, but may actually stimulate growth of *Pseudomonas*. It should not be administered to patients with iatrogenic meningitis. Of 23 cases collected from the literature in which streptomycin was given either intrathecally, parenterally, or combined, 15 were cured and 8 died. In the authors' female patient, *Pseudomonas aeruginosa* was resistant to penicillin, bacitracin, streptomycin, and chlortetracycline (Aureomycin), but was moderately sensitive to both oxytetracycline (Terramycin) and chloramphenicol (Chloromycetin); a complete cure was obtained with the two latter drugs. Recovery of the man was obtained with streptomycin given by intramuscular and intrathecal routes. Polymyxin was effective in the few reported trials. Neomycin proved effective in two cases. Effective therapy depends on proper identification and sensitivity tests of the organism involved.

Advantages and Risks of Preserving Ovary After Age 45.—

The advantages of preserving the ovaries when operating on women over 45 are often regarded as not sufficiently important to warrant the risk that a malignant lesion may develop if an ovary is not removed at the time of hysterectomy. Physicians and laboratories in the state of New York for the past 12 years have been reporting all malignant tumors to the Division of Cancer Control. From the information thus obtained the authors estimate that the calculated risk of preserving the ovary, at least in women "over fifty," would appear to be that, in 1,000 women subjected to pelvic laparotomy, in 8 a malignant and in 6 a benign neoplasm will develop, all of which

could have been prevented if both ovaries had been removed at laparotomy. They doubt that this warrants the removal of normal-appearing ovaries merely as a prophylactic measure. The chance of bilateral involvement, not grossly appreciable but already developing in the other ovary, does indicate careful inspection and bisection of the opposite ovary before it can be regarded as normal and uninvolved by a neoplasm involving one side. When contemplating the prophylactic removal of ovaries in women over 45, account should be taken of two facts: In a review of over 1,100 benign cystomas it was found that approximately 70% had developed before the age of 45, and the probability of a malignant lesion developing in a woman's ovary is now known to decrease rapidly after her 50th year.

Unlimited Diet in Peptic Ulcer.—It was Marshall's aim to set up a schedule that would permit the ulcer patient to eat and drink everything without distress at the end of 24 hours. While this can be done in many ways, the author feels that the use of combination tablets is the simplest method. Aluminum hydroxide, because of its adsorptive properties, was the basic treatment in most of the 1,000 patients treated by the author. A no. 2 tablet, which contained calcium carbonate, 0.5 gm., magnesium oxide, 0.25 gm., phenobarbital, 0.016 gm., and atropine, 0.0002 gm., was compounded to furnish neutralization and sedation and to combat the constipating effect of aluminum hydroxide. This tablet was effective, but had a somewhat excessive laxative effect, and so in a no. 3 tablet the magnesium oxide was dropped and the calcium carbonate increased to 0.65 gm. With the use of the three tablets—first, a 0.65 mg. tablet of aluminum hydroxide and tablets or capsules no. 2 and no. 3—the schedule is usually set up on an ambulatory basis. Assuming that the patient arises at 6:30 a. m. and retires at 11 p. m., he is given two tablets (1.3 gm.) of aluminum hydroxide at 6:30, 7:30, 8:30, etc., every hour on the half-hour until 10:30 p. m. Then, at 11 p. m., 1 a. m., and 3 a. m. the aluminum hydroxide dose is increased to four tablets (2.6 gm.) and, unless milk allergy is present, 240 cc. of whole milk is given in addition on each of these three hours. As to the no. 2 and no. 3 tablets, the daily dose is nine tablets crushed (or capsules). Usually with the above 44 tablets (28.6 gm.) of aluminum hydroxide, the schedule will call for six no. 2 and three no. 3 tablets, that is, one no. 2 at 7 and 9 a. m. and 1, 3, 7 and 9 p. m. with one no. 3 at 11 a. m. and 5 and 11 p. m. with the first night feeding if bowel habits continue to be normal. The author stresses that the more frequent the medication the better and warns that the dose and frequency should not be cut for a minimum of four and one-half months. Unlimited diet was successfully given in 921 of the 1,000 ulcer patients treated. The advantages of this treatment include the

following factors. 1. It presents immediate evidence of inadequate therapy. 2. It permits a more nutritious diet. 3. Because of the rapid disappearance of the niche under heavier therapy, the differentiation of malignant from benign gastric ulcer is aided. 4. Separation of surgical from medical hemorrhagic cases is accomplished in 24 hours. A patient who bleeds on "heavy" therapy is not likely to stop on further medical treatment. 5. Over 95% of the obstructed, nonstenotic cases may be salvaged and the surgical cases are apparent immediately. 6. Ulcer patients like to eat and unlimited diet adds to their security. 7. Serious complications are diminished when this method is followed. 8. The period between cessation of therapy and recurrence is greatly extended. The fact that the average ulcer patient was seen by his physician about every six weeks, or about three or four times, and the long symptom-free period greatly diminishes the cost of treatment of peptic ulcer.

Treatment of Acute Bacterial Meningitis.—The study reported by Smith and Herring was designed to evaluate the results obtained when all patients with "purulent meningitis" were treated according to the same regimen, regardless of causative organism. Bacteriological studies were carried out so that it would be possible in retrospect to evaluate the treatment in each type of meningitis. Of the 98 patients with meningitis admitted to the contagious disease service of the Tulane Pediatric Department at Charity Hospital, 86 were included in the present analysis. On admission a lumbar puncture was performed and the pressure was determined; spinal fluid was obtained for smear, culture, cell count, and chemical analysis. The patient was then given sodium sulfadiazine intravenously (50 mg. per kilogram of body weight) and aqueous penicillin (200,000 units intravenously). At the same time sulfadiazine was given by mouth or by stomach tube (100 mg. per kilogram of body weight), also chloramphenicol (100 mg. per kilogram of body weight). Subsequent medication consisted of sulfadiazine (150 mg. per kilogram of body weight daily, divided into four or six doses); chloramphenicol (250 mg. every 6 or 8 hours, depending on the size of the child); and aqueous penicillin (200,000 units intramuscularly every 8 hours). Treatment was continued for a minimum of six days or until the patient had been afebrile for 48 hours, whichever was longer. All of the patients were less than 10 years old, and 51, or considerably over half, of the 86 children were less than 2 years old; that is, they belonged to the age group in which mortality is likely to be highest. Seven of the 86 children died (8.1%). Bacteriological studies showed that in 32 patients *Hemophilus influenzae* was the causative agent, in 26 the meningococcus; in 14 the pneumococcus. In 14 the causative agent could not be identified. Analysis of the data suggests that, where reliable bacteriological help is not available, the above three drugs in combination may be used in the treatment of any child, more than 2 to 3 months of age, with purulent meningitis with expectation of a satisfactory outcome. An unusually high incidence of complications in patients with *H. influenzae* meningitis who were treated with the palmitate-ester of chloramphenicol suggests that this compound is to be avoided in children who have severe, acute infections.

Diagnosis and Treatment of Migraine and Tension Headache.—Periodicity and recurrence, positive family history, cortical phenomena, gastrointestinal disturbance, unilateral nature as well as shifting location of pain in the head, and positive response to ergotamine products indicate a diagnosis of migraine. If most or all of these characteristics are present, the migraine is typical, but oftener it appears in an atypical form. Typical migraine has three vascular phases, namely (1) vasoconstriction, (2) vasodilatation, and (3) edema. During the usually short (half hour), prodromal phase vasoconstriction involving the intracranial arteries occurs and produces scotoma, hemianopsia, paralysis, diplopia, paresthesia, and aphasia. During vasodilatation, headache is experienced, and associated symptoms are anorexia, nausea, vomiting, diarrhea, dizziness, fever, palpitation, and excessive perspiration and urination. There may be flushing or pallor of the face, reddening of the conjunctivas, and nasal congestion. Although the stage of edema is not commonly seen, when observed, it is characterized by swollen, hard, and tender extracranial vessels on the side of the headache. The throbbing headache of the vasodilating phase evolves into a constant sharp pain with tenderness, usually in the frontal, temporal, and parietal regions, that lingers until the attack has subsided. During this phase vasoconstrictive agents are not only ineffective but may aggravate the pain. The history is the most important diagnostic aid, but provocative tests with nitroglycerin sublingually, histamine subcutaneously, or nicotinic acid are helpful. "Tension headache" is a pain in the head arising from "tension," a state of nervous hyperirritability, which results from emotional stimulation or conflict. Migrainous patients often say, "I have two kinds of headache" and describe the dull, generalized headache of tension type and a severer type that comes periodically, perhaps once or twice a week or month. This is throbbing, unilateral (although it can be bilateral), and associated with nausea, photophobia, and perhaps vomiting. The migraine headache responds to ergotamine products, while the tension headache will not. Migraine is almost always associated with nervous tension. Drug therapy is usually enough to abort a mild attack, but, when moderate or severe, the migrainous attack becomes resistant to drug therapy and at times nothing is effective except sleep-inducing agents. The different vascular phases of migraine must be considered during treatment. Thus, during the early vasoconstriction, vasodilators such as nicotinic acid, in doses of 100 to 200 mg. by mouth, may abort the cortical phenomena, or inhalation of 10% carbon dioxide with 90% oxygen may be used, if nicotinic acid is not effective. During vasodilatation the vasoconstricting drugs are most important. However, many patients will get relief from simple measures such as aspirin or rest. One of the best vasoconstricting preparations is cafergot, a tablet containing 100 mg. of caffeine alkaloid and 1 mg. of ergotamine tartrate. For severer attacks, dihydroergotamine is recommended. Patients who have migraine as well as tension headaches must learn to rest and relax, to avoid fatigue. While migraine cannot be cured, much relief can be provided.

for the administration of 1 gm. of streptomycin is no more difficult than that required for the administration of 200,000 units of penicillin in aqueous suspension. Combined treatment with streptomycin parenterally and sulfathiazole orally proved highly effective in both gonococcal and nongonococcal urethritis. Where an immediate microscopic diagnosis cannot be made, concurrent combined therapy with streptomycin and sulfathiazole is recommended for the treatment of urethritis in preference to penicillin therapy that is ineffective in the treatment of most patients with nongonococcal urethritis and carries with it the risk of masking the development of syphilis.

Assessment and Results of Obesity.—Obesity, in which the amount of body fat is greater than normal, should be distinguished from overweight, in which the body weight is greater than normal in relation to such factors as race, sex, body type, height, and age. Obesity cannot be satisfactorily assessed by measuring the body weight, but it can be estimated with reasonable accuracy in adults by determining the thickness of the subcutaneous tissue, in which approximately half the amount of fat in the body is found. The problem of assessment is more complicated in children, because of the spurts in growth to which they are subject and because the distribution of subcutaneous fat varies with age. Overnourishment during growth, which leads to early maturity and a shortened life span in the lower animals, is probably harmful to children. Statistics show that at all ages men and women who are overweight have a higher mortality than the average, and the greater the degree of obesity the greater the mortality. Obesity is a forerunner of diabetes from middle life onward in fully 90% of the cases, and atherosclerosis is most frequent among the obese. Both of these conditions are characterized by an increase in the formation of cholesterol. Hereditarily obese mice in the prediabetic phase may be likened to patients with hypothalamic obesity; both have increased lipogenesis, which causes them to overeat. Diabetes characterized by a high degree of insulin resistance develops by the 9th or 10th week of life in these mice and results in their premature death. Obese mice in which insulin-resistant diabetes has appeared may be likened to the middle-aged obese diabetic; both have hypercholesterolemia. There is no relation between the serum cholesterol level and the habitual dietary intake of cholesterol, but increases in the amount of dietary fat, which tend to produce obesity, will raise the serum cholesterol and result in atherosclerosis. Weight reduction substantially lowers mortality and decreases the incidence of diseases connected with obesity among the overweight.

 *Erythema Multiforme Exudativum; Etiological Study of Idiopathic Type. M. Ruiter and H. Hamminga.—p. 418.

Erythema Multiforme Exudativum.—In recent years internists, rather than dermatologists, emphasized the great importance of *Mycobacterium tuberculosis* and *Streptococcus hemolyticus* as causative agents for erythema multiforme exudativum. At the dermatological department of the University of Groningen, Netherlands, 17 patients with typical erythema multiforme exudativum, corresponding in every respect with the criteria established by Hebra, were studied by the authors concerning these two causative agents. Results of Pirquet's and Mantoux tests, roentgenologic examination of the lungs of the patients,

otolaryngological and dental examination for local foci, and serologic examinations for streptococcal infections did not furnish any evidence in these patients of either causative agent. The authors believe this discrepancy can be explained by the fact that those workers have not sufficiently differentiated the classic forms of erythema multiforme exudativum from the somewhat similar erythema multiforme syndrome. The cutaneous manifestations of the erythema multiforme syndrome are much less characteristic than the well-defined patch or the flat papule described by Hebra as the primary florescence of a typical case of erythema multiforme exudativum. While the simultaneous occurrence of erythema nodosum has not been observed with the idiopathic type, such combined occurrence is not rare with the erythema multiforme syndrome, particularly in those cases in which internal disease processes, particularly tuberculous or streptococcal infections, and occasionally even drug hypersensitivity, form the basis for the cutaneous manifestations. While the causative factors of erythema multiforme exudativum are still unknown, the syndrome can be produced by many different causative factors. Any clinical diagnosis that is not based on morphological factors and is, therefore, not sufficiently distinctive must lead to errors. In the future the study of the causative factors must distinguish sharply between the two discussed groups on the basis of clinical morphology.

 *Treatment of Arterial Hypertension with Rauwolfia Alkaloid Reserpine (Serpasil). G. Damm and H. Trautner.—p. 39.

Aminophylline in Initial Phase of Apoplectic Attack.—In 1949, Mainzer introduced the treatment of the initial phase of an apoplectic attack with intravenous injections of aminophylline (Euphyllin). Up to December, 1952, 126 cases were reported by the author in previous papers and by other workers in which favorable results were obtained with this method. It appeared that the aminophylline is fully effective only when given in the ischemia-conditioned functional phase of the apoplectic attack. The percentage of success is reduced from 80 to 45% in patients to whom the drug was given within five hours after the attack. The drug should be given within one hour of the initial attack, although coma and mild paresis disappeared in two of the author's patients who were given the drug within eight hours, and one patient responded favorably to the drug given 11 hours after the initial attack. The author emphasizes the importance of the intravenous route of administration, while oral, rectal, or intramuscular administration may result in failure. Refractory headache in patients with cerebral arteriosclerosis and hypertension (one illustrative case in an 84-year-old woman is described) responded favorably to aminophylline. Increased permeability of the blood-cerebrospinal fluid barrier produced by the aminophylline is probably responsible for its effect in the initial stage of the apoplectic attack.

Rauwolfia Alkaloid Reserpine in Hypertension.—Reserpine (Serpasil), was given a therapeutic trial in 44 patients with arterial hypertension in whom the high blood pressure had not been significantly reduced by bed rest, salt-free diet, and occasional digitalization for three to six weeks. These measures were continued after the institution of reserpine. The drug was given in three tablets, each of 0.5 mg., daily; three patients received up to six tablets daily. Marked lowering of the blood pressure was obtained in 20 of the 44 patients with all types of arterial hypertension. The drop in blood pressure exceeded that obtained with the usual hospital procedures. Parallel improvement of subjective complaints was observed in many patients. Lowering of blood pressure resulted from combined treatment with reserpine and Nepresol (1, 4-dihydrazinophthalazine) in nine patients who did not respond to reserpine alone. A condition

*Chylous Ascites in Infants in Course of Primary Intestinal Tuberculosis. H. Beyer.—p. 249.

Chylous Ascites in Infants with Primary Intestinal Tuberculosis.—The occurrence of chylous ascites is reported in a 5½-month-old baby boy in whom primary intestinal tuberculosis was diagnosed on roentgenologic examination. Severe inflammatory (tuberculous) changes of the small intestine were observed. Multiple intra-abdominal calcifications demonstrated the extensive involvement of the lymph nodes of the mesentery. Chyle stasis may be considered in addition to inflammatory changes of the walls of the chyliferous vessels (tuberculous lymphangitis). An inflammatory process was suggested in the author's case and in other cases collected from the literature by the fact that recovery resulted from repeated abdominal puncture or pneumoperitoneum. Both procedures are not to be considered as causal treatment. The abdominal puncture in the author's case probably stimulated the peritoneum in the sense of absorption besides causing mechanical discharge. The protein values of the ascitic fluid, which initially were higher than those in the blood, with an increased amount of globulin, also favored the concept of an inflammatory component. In the retroperitoneal space, which may be assigned a key position in the causation of the chylous ascites, are seen converging (1) the lymph vessels of the lower extremities and the pelvic organs; (2) the lymph vessels of a major portion of the deeper layers of the abdominal wall; (3) the lymph vessels of the kidneys, adrenals, and the inferior surface of the diaphragm; (4) the lymph vessels of the stomach, spleen, pancreas, and liver, which are connected with the celiac lymph nodes; and (5) the chyle vessels of the intestine. The lymph nodes of the retroperitoneal space form a chain with the lymph vessels that run toward the cranium. This chain passes along the vena cava inferior and the abdominal aorta and is connected with the iliac-lumbar lymph nodes that pass along the iliac artery and vein. These anatomic relations explain some of the idiopathic cases reported in the literature. The author believes that the extent of the participation of the chyliferous vessels in the distal portions of the ileum-jejunum segment is so extensive that a "collateral circulation" does not become effective because of the involvement of numerous anastomoses of the lymph system in the mesentery, or that the exudation from the chyliferous vessels must be sufficient for the production of a chylous ascites.

Therapeutics of Nongonococcal Urethritis.—Of 769 patients with primary nongonococcal urethritis of venereal origin, (33 of whom had Reiter's disease), 208 were treated with oxytetracycline (Terramycin), 316 with chlortetracycline (Aureo-

mycin), 93 with chloramphenicol (Chloromycetin), 86 with streptomycin sulfate, 52 with dihydrostreptomycin, and 14 with streptomycin calcium chloride. The dosage of oxytetracycline, chlortetracycline, and chloramphenicol was 0.5 gm. every six hours for four days; when blood-borne complications were present the treatment was continued for 10 to 14 days. The dose of chloramphenicol was later increased to 0.75 gm. given every six hours, as the lower dose was frequently ineffective. The streptomycin preparations were given in a dose of 1 gm. in 4 cc. of water once daily for five days and twice daily for 10 to 14 days in cases of Reiter's disease. Chlortetracycline and oxytetracycline in particular attain a high concentration in the urine, and the therapeutic effect can be enhanced by restricting fluid intake by one-half during the treatment and by instructing the patients to pass urine frequently however small the amount. Infection with Trichomonas vaginalis was present in 59 patients and was resistant to the antibiotic treatment. Vaginal and/or cervical swabs gave positive cultures for pleuropneumonia-like organisms in 28 of 55 patients (51%); six strains were completely insensitive to dihydrostreptomycin and chlortetracycline in concentrations that would be present in the blood, moderately sensitive to streptomycin and chloramphenicol, and very sensitive to oxytetracycline in vitro. Elementary bodies of inclusion conjunctivitis type were seen in 10 patients. In patients who responded to treatment, the discharge ceased in two to four days and symptoms disappeared in one to seven days. The following cure rates were obtained: 86.5% with oxytetracycline; 63% with chlortetracycline; 39% with streptomycin; and 36% with chloramphenicol. A cure was also obtained with oxytetracycline in 24 of 31 patients who had not responded to chlortetracycline. The apparent superiority of oxytetracycline was confirmed by statistical analysis in a second series of 156 patients who were treated with the same drugs as the 769 patients but who were given these drugs at random to avoid any inclination on the part of the physician to give patients with severe disease the drug that was thought to be best, and to patients with mild disease the drug that might seem to effect a certain cure. The following cure rates were obtained: 87% with oxytetracycline; 59% with chlortetracycline; 38% with streptomycin; and 31% with chloramphenicol. Patients with Reiter's disease were best treated with fever therapy combined with oxytetracycline or chlortetracycline.

Treatment for Gonococcal and Nongonococcal Urethritis.—A search was made for a therapeutic procedure that would achieve success in the treatment of both gonococcal and nongonococcal urethritis when the circumstances were such that a microscopic diagnosis before the treatment was impracticable and at the same time would eliminate the risk of the development of a coincidentally acquired syphilis. After an extensive review of the literature on treatment of gonococcal and nongonococcal infections of the urinary tract and of syphilis with sulfonamides alone, with various antibiotics, and with sulfonamides combined with antibiotics, it was decided that every patient with urethritis, whether gonococcal or nongonococcal, should be given a course of combined streptomycin-sulfathiazole therapy. Thus 325 men with gonorrhea and 215 men with nonspecific urethritis treated in two clinics between July 1, 1952, and March 31, 1953, were given a dose of 1 gm. of streptomycin or dihydrostreptomycin by deep subcutaneous injection together with 6 gm. of sulfathiazole in four divided doses daily for five days (total dose: 5 gm. of streptomycin and 30 gm. of sulfathiazole). An average cure rate of 90% was obtained with this combined therapy in 292 patients with gonorrhea and nonspecific urethritis followed up for 12 or more days after initiation of treatment; 169 (92.8%) of 182 patients with gonorrhea and 94 (85.4%) of 110 patients with nonspecific urethritis were considered successfully treated. Urethral discharge was eliminated within 48 hours of the start of the treatment in 238 patients (96.7%) of 246 patients with gonorrhea and in 152 (92.1%) of 165 patients with nonspecific urethritis examined on the second day of the treatment. No toxic effects attributable to streptomycin were observed. Of the 540 patients treated, 394 were followed up for five days or more, and only 5 (1.26%) of the 394 showed toxic signs attributable to sulfathiazole. The injection technique required

for the administration of 1 gm. of streptomycin is no more difficult than that required for the administration of 200,000 units of penicillin in aqueous suspension. Combined treatment with streptomycin parenterally and sulfathiazole orally proved highly effective in both gonococcal and nongonococcal urethritis. Where an immediate microscopic diagnosis cannot be made, concurrent combined therapy with streptomycin and sulfathiazole is recommended for the treatment of urethritis in preference to penicillin therapy that is ineffective in the treatment of most patients with nongonococcal urethritis and carries with it the risk of masking the development of syphilis.

Assessment and Results of Obesity.—Obesity, in which the amount of body fat is greater than normal, should be distinguished from overweight, in which the body weight is greater than normal in relation to such factors as race, sex, body type, height, and age. Obesity cannot be satisfactorily assessed by measuring the body weight, but it can be estimated with reasonable accuracy in adults by determining the thickness of the subcutaneous tissue, in which approximately half the amount of fat in the body is found. The problem of assessment is more complicated in children, because of the spurts in growth to which they are subject and because the distribution of subcutaneous fat varies with age. Overnourishment during growth, which leads to early maturity and a shortened life span in the lower animals, is probably harmful to children. Statistics show that at all ages men and women who are overweight have a higher mortality than the average, and the greater the degree of obesity the greater the mortality. Obesity is a forerunner of diabetes from middle life onward in fully 90% of the cases, and atherosclerosis is most frequent among the obese. Both of these conditions are characterized by an increase in the formation of cholesterol. Hereditarily obese mice in the prediabetic phase may be likened to patients with hypothalamic obesity; both have increased lipogenesis, which causes them to overeat. Diabetes characterized by a high degree of insulin resistance develops by the 9th or 10th week of life in these mice and results in their premature death. Obese mice in which insulin-resistant diabetes has appeared may be likened to the middle-aged obese diabetic; both have hypercholesterolemia. There is no relation between the serum cholesterol level and the habitual dietary intake of cholesterol, but increases in the amount of dietary fat, which tend to produce obesity, will raise the serum cholesterol and result in atherosclerosis. Weight reduction substantially lowers mortality and decreases the incidence of diseases connected with obesity among the overweight.

 *Erythema Multiforme Exudativum; Etiological Study of Idiopathic Type. M. Ruiter and H. Hamminga.—p. 418.

Erythema Multiforme Exudativum.—In recent years internists, rather than dermatologists, emphasized the great importance of *Mycobacterium tuberculosis* and *Streptococcus hemolyticus* as causative agents for erythema multiforme exudativum. At the dermatological department of the University of Groningen, Netherlands, 17 patients with typical erythema multiforme exudativum, corresponding in every respect with the criteria established by Hebra, were studied by the authors concerning these two causative agents. Results of Pirquet's and Mantoux tests, roentgenologic examination of the lungs of the patients,

otolaryngological and dental examination for local foci, and serologic examinations for streptococcal infections did not furnish any evidence in these patients of either causative agent. The authors believe this discrepancy can be explained by the fact that those workers have not sufficiently differentiated the classic forms of erythema multiforme exudativum from the somewhat similar erythema multiforme syndrome. The cutaneous manifestations of the erythema multiforme syndrome are much less characteristic than the well-defined patch or the flat papule described by Hebra as the primary florescence of a typical case of erythema multiforme exudativum. While the simultaneous occurrence of erythema nodosum has not been observed with the idiopathic type, such combined occurrence is not rare with the erythema multiforme syndrome, particularly in those cases in which internal disease processes, particularly tuberculous or streptococcal infections, and occasionally even drug hypersensitivity, form the basis for the cutaneous manifestations. While the causative factors of erythema multiforme exudativum are still unknown, the syndrome can be produced by many different causative factors. Any clinical diagnosis that is not based on morphological factors and is, therefore, not sufficiently distinctive must lead to errors. In the future the study of the causative factors must distinguish sharply between the two discussed groups on the basis of clinical morphology.

 *Treatment of Arterial Hypertension with Rauwolfia Alkaloid Reserpine (Serpasil). G. Damm and H. Trautner.—p. 39.

Aminophylline in Initial Phase of Apoplectic Attack.—In 1949, Mainzer introduced the treatment of the initial phase of an apoplectic attack with intravenous injections of aminophylline (Euphyllin). Up to December, 1952, 126 cases were reported by the author in previous papers and by other workers in which favorable results were obtained with this method. It appeared that the aminophylline is fully effective only when given in the ischemia-conditioned functional phase of the apoplectic attack. The percentage of success is reduced from 80 to 45% in patients to whom the drug was given within five hours after the attack. The drug should be given within one hour of the initial attack, although coma and mild paresis disappeared in two of the author's patients who were given the drug within eight hours, and one patient responded favorably to the drug given 11 hours after the initial attack. The author emphasizes the importance of the intravenous route of administration, while oral, rectal, or intramuscular administration may result in failure. Refractory headache in patients with cerebral arteriosclerosis and hypertension (one illustrative case in an 84-year-old woman is described) responded favorably to aminophylline. Increased permeability of the blood-cerebrospinal fluid barrier produced by the aminophylline is probably responsible for its effect in the initial stage of the apoplectic attack.

Rauwolfia Alkaloid Reserpine in Hypertension.—Reserpine (Serpasil), was given a therapeutic trial in 44 patients with arterial hypertension in whom the high blood pressure had not been significantly reduced by bed rest, salt-free diet, and occasional digitalization for three to six weeks. These measures were continued after the institution of reserpine. The drug was given in three tablets, each of 0.5 mg., daily; three patients received up to six tablets daily. Marked lowering of the blood pressure was obtained in 20 of the 44 patients with all types of arterial hypertension. The drop in blood pressure exceeded that obtained with the usual hospital procedures. Parallel improvement of subjective complaints was observed in many patients. Lowering of blood pressure resulted from combined treatment with reserpine and Nepresol (1, 4-dihydrazinophthalazine) in nine patients who did not respond to reserpine alone. A condition

similar to collapse resulted from the pronounced reduction of blood pressure in two patients with severe arteriosclerotic changes. It seems that reserpine reduces the blood pressure by exerting an effect on the central nervous system. Lowering of blood pressure was likewise obtained in some patients with phenobarbital, bed rest and salt-free diet. Phenobarbital also acts as a depressor agent on the central nervous system.

Toxicity of Chloroquine in Hepatic Amebiasis.—Chloroquine sulfate was used in the treatment of 112 Bantu Africans with hepatic amebiasis. Toxic reactions were noted in 52, and were severe in 10. The toxic effects were unpleasant, but not fatal, and they were directly related to the dosage of the drug and to the length of treatment. Women had severer toxic reactions than men. Vomiting sometimes required that use of the drug be stopped. The toxic effects were reversible, passed off within 48 hours after medication had been discontinued, and caused no permanent damage. Chloroquine may have a temporary toxic effect on the nervous system. It is assumed that the greater incidence of toxic reactions in these patients was caused by their poor physical condition. They were smaller in stature and lighter in weight than Europeans, also they were malnourished. Chloroquine should be used with caution in persons in whom blurring of vision and giddiness may have dangerous results, such as in drivers and pilots. These should not be allowed to continue their work while being treated with chloroquine, at least in the doses required in amebiasis.

Electroencephalography in Differentiation of Neuroses and Organic Brain Disease.—Stehle feels that because some types of organic brain damage and certain types of epilepsy are symptomatically difficult to distinguish from neurosis, it should be advantageous to obtain electroencephalographic studies on all neurotics. However, since such mass electroencephalography is not practical, patients should be screened by the physician or the electroencephalographer so that recordings are made only in cases in which there is a reasonable expectation of significant electroencephalographic findings. For some years this policy has been carried out at the author's clinic. The present study was undertaken to assess the value of electro-

encephalography as an aid to the diagnosis of neurosis using currently accepted criteria for referral. Answers were sought to the following questions: 1. What is the type and incidence of electroencephalographic abnormality in patients with a presumed diagnosis of neurosis who are referred for electroencephalographic examination? 2. With what "neurotic" symptoms do electroencephalographic abnormalities correlate? The 263 veteran patients studied by electroencephalography were highly selected, not representative of all neurotics, but only those who (though presumably neurotic) were suspected of having organic brain disorder. Awake and sleep electroencephalograms were obtained in 200 cases and only awake records were obtained in 63 cases. Electroencephalograms made during sleep in 200 patients revealed significant abnormalities with clinical correlation in 19%, seizure discharges accounting for 14%. In the group examined only when awake, the incidence of significant abnormalities with clinical correlation was much lower. Epileptic seizure discharges were never recorded in the electroencephalogram made while awake but only during the drowsy or sleep state. This seems to indicate the advantage of making studies during sleep. The author feels that the following generalization is permissible; the less severe the abnormality the more essential is electroencephalographic study during sleep. The diagnostic use of electroencephalographic study appears indicated in neurotic patients with symptoms such as major convulsions, abdominal complaints, amnesia, visual disturbances, rage attacks, nausea and vomiting, and weakness-fainting-blackouts. This appears especially true if the clinical history gives any indication of a previous head injury or cerebral infection. It was found that 27.5% of those showing normal electroencephalographic records during sleep gave a history of cerebral trauma or infection, but 45% of those showing abnormal electroencephalographic findings gave such a history. In the groups with psychomotor, thalamic, and hypothalamic epilepsy 50% had a history of head injury.

 *Functional Uterine Haemorrhage in Puberty and Adolescence. A. M. Sutherland.—p. 496.

Uterine Hemorrhage in Puberty and Adolescence.—Sutherland made studies on 200 girls, 20 years of age or younger, who had abnormal uterine bleeding. Of these, 179 girls were between 16 and 20 years of age. Sixteen of the 200 had been pregnant, 9 having had one delivery at full term and the other 7 having had one abortion. He is of the opinion that it is impossible to make a diagnosis of functional uterine bleeding until the endometrium has been examined histologically. Dilatation and curettage was done in all but one of the 200 girls. In the patient not subjected to curettage uterine fibroids of about the size of a four month pregnancy were present and hysterectomy was necessary. In those with a reasonably regular cycle curettage was done during the premenstrual phase. Tuberculosis of the endometrium was found in 8 cases and chronic endometritis in 10 cases. Cystic glandular hyperplasia was found in only 31 cases and endometrial atrophy in 4 cases. In the remaining 147 cases the endometrium appeared normal. An attempt was made to follow-up as many as possible of the last 50 patients. They were asked to report in two months, and subsequent attendances varied with the individual case. Two patients with endometrial tuberculosis were excluded from this follow-up. They were treated with streptomycin and *p*-aminosalicylic acid. Of the remaining 48 cases 5 could not be traced. In 20 of 43 patients, menstruation remained normal after dilatation and curettage alone during an average follow-up period of 11 months. In six others menstruation returned to normal after curettage, but abnormal bleeding recurred after an average period of six months. There was no relationship between the endometrial histology and the results of curettage. In three of six cases of endometrial hyperplasia, the curettage had no effect, and in the three others it was followed by a return to a normal cycle. The antimenorrhagic factor, which is a non-

saponifiable fraction of mammalian liver tissue suspended in a neutral base, was used in 19 of the remaining 23 patients. Cure was obtained in 12, but in 6 of these a second course of the drug had to be given. One other patient failed to return, and in the remaining six patients the antimenorrhagic factor was ineffective. Treatment with estrogen preparations proved effective in four of the six cases in which it was tried.

Tuberculosis Transmitted by Banked Bone.—James says that during the last year ribs from thoracoplasties performed in cases of pulmonary tuberculosis have been stored in the bone bank. The ribs have been frozen at -15 to -20 C in a solution containing penicillin and streptomycin. They have been used in a wide variety of orthopedic procedures. In the last months four tuberculous abscesses have been discovered. After removal of the infected bone chips and curettage, the wounds healed without further incident; it is possible that further manifestations may appear. This unfortunate sequel makes it obvious that such material is unsuitable for bone grafting. The four cases are briefly described.

Mesenchymoma (Angioliposarcoma) of Thigh.—According to Pemberton and Cromack the term mesenchymoma was first applied by Gilmour in 1943 to an unusual recurring tumor composed of embryonic connective tissue. This tumor appeared histologically benign, but recurrences developed after every attempt at local removal. Since then, three more cases of a similar character have been described by Symmers and Nangle (1951), who also recorded the fatal termination of Gilmour's case. Pemberton and Cromack present two cases of mesenchymoma occurring in the thigh of two women, aged 47 and 50, respectively. In the first patient the limb was removed by disarticulation at the hip joint, all the muscles being divided as high as possible. One year after the operation the patient was in good health and there was no sign of recurrence. The tumor was ovoid and soft and measured 19 by 15 cm. It was partly surrounded by a thin diaphanous capsule. On gross section the tumor was separated into lobules by fibrous septa. It encircled the femur for almost three-quarters of its circumference, extended upwards from the knee joint to the uppermost limits of the vastus intermedius. Although it was mainly confined to the quadriceps group, it involved also the insertion of the adductor muscles into the shaft of the femur. Microscopic examination disclosed angioblastic, fibroblastic, and lipoblastic tissues. In the second patient an extensive local excision had been done at another hospital. When one year later a recurrence was observed, it was removed together with the fascia of the surrounding muscles. There was a further recurrence one year later; local excision was again undertaken. There was yet another local recurrence nine months later, again treated by excision. At the fourth operation it was obvious that the tumor was infiltrating the surrounding tissues. Amputation was, therefore, undertaken four years after the onset of symptoms and three years after the first local excision. One year after amputation there was no evidence of a return of the lesion. The term mesenchymoma is appropriate, because of the resemblance of the primitive fibroblastic component of the tumor to mes-

enchymal tissue. Confusion in terminology may arise, however, because the term mesenchymoma has also been applied to other tumors such as myxomas, mixed malignant tumors of mesodermal origin, and even to undifferentiated sarcomas. The two cases presented conform to the pattern of Gilmour's case to which he applied the description mesenchymoma. Since recurrence seems invariably to follow local removal a relatively drastic surgical policy is justifiable and indeed necessary.

Intravenous Use of Procaine in Chest Wall Injuries.—Bevan tried procaine for the relief of pain associated with chest wall injuries. The injury was often minor, though some cases of major trauma were also included. The pain was of three types—localized to the site of injury, diffusely spread over a wide area of the chest, or referred forward along the intercostal nerves. Coughing, inspiration, and movement of the trunk or upper limb were often much restricted. The procaine was injected into a vein of the forearm from a 20 ml. syringe. After various modifications, the standard dose adopted for a normal adult was 20 ml. of 1% procaine, with adjustment for age and physique. At first the injections were given slowly over 15 minutes; but later the time was reduced to 5 minutes. Each injection was given with the patient recumbent, to counteract the vasodilator effect of procaine. He then rested half an hour and was sent home by ambulance. He was seen again next day and again a few days later. The procaine was prepared in sealed 20 ml. ampuls and contained no epinephrine (Adrenaline) or bacteriostatic. Convulsions, which may lead to respiratory paralysis, and peripheral vascular failure resulting from medullary depression are dangers in procaine therapy, which are probably due to idiosyncrasy. To safeguard the patients against these threats a tray was at hand containing thiopental (Thiopentone) sodium to antagonize the convulsant action of procaine and ephedrine to combat the medullary depression. However, in giving 82 injections there was no need to use these drugs. In three cases the patient lost consciousness and in two speech was lost, but these effects were transient. In two elderly men the pulse was irregular for an hour. Pain was relieved in the large majority of the patients, and their respiratory function and general condition improved. The relief was greater in fractures than in soft tissue injury, and the benefit was greatest when the injection was given soon after the injury. The relief was immediate or was delayed for a few hours. It lasted for about 20 hours. A second injection was never so effective as the first. Estimation of procaine levels in blood and urine confirmed that procaine is excreted from the blood within an hour. Its effect over hours or days is probably not due to continuing anesthetic action but to a breaking of the vicious circle of pain to muscle spasm to pain. In control cases, intravenous injections of isotonic sodium chloride solution were of some benefit, but it was much less than with procaine.

Vitamin K₁ and Anticoagulant Therapy.—Synthetic vitamin K₁ (Konakion) was administered to four patients receiving Marcoumar (3[1'-phenyl-propyl]4-hydroxycoumarin) and three receiving ethyl biscoumacetate (Tromexan ethyl acetate). The good effects of the vitamin, which was given orally in doses of 10 to 12 mg., became evident in most instances six hours after its administration. In one patient receiving Marcoumar, the prothrombin time was shortened from 70 to 32 seconds in 10 hours and from 32 to 28 seconds in the next 24 hours. Twelve hours after the administration of a second 10 mg. dose of the vitamin, it was reduced to 23 seconds. Equally good effects were obtained in the other six patients. Similar results have been reported by American and English authors. They, however, had given their patients a single dose of 500 mg. of the vitamin, whereas Gagliardi never used more than from 10 to 24 mg. of it. Synthetic vitamin K₁ greatly improves the prognosis of patients receiving anticoagulants with a bishydroxycoumarin-like action, because with its administration the hemorrhagic complications secondary to this therapy can be prevented.

Minerva Medica, Turin

Cortisone Therapy in Tetanus.—Three patients with tetanus were given cortisone as supplement to antitoxin serum and penicillin. Although the authors could not judge what part the hormone played in attenuating the course of the disease, they say that it did have a favorable effect on the clinical course and brought relief to the patients by rapidly lowering the elevated temperature, reducing the intensity and number of spasms, and improving the patients' vital sense and appetite. The first patient, a 5-year-old girl, was hospitalized with a diagnosis of meningitis. After the presence of tetanus was established, she was given antitoxin serum, penicillin, and cortisone. She received the hormone first in two 50 mg. injections and later in one 50 mg. injection daily for a total of 1,500 mg. She recovered in about two weeks. Antiserum and penicillin were given to the second patient, a 5-year-old girl, but her already severe condition was aggravated by the therapy. Cortisone was then administered in doses of 200 mg. for one day, 100 mg. for 6 days, and 50 mg. for 4 days. There was a noticeable improvement with the cessation of spasms and recovery. The severe infection was undiagnosed in the third patient, a 64-year-old woman. A correct diagnosis was established, massive tetanus was confirmed, and, in addition to antitoxin serum and penicillin, 300 mg. of cortisone was given for three days, 100 mg. for seven days, and 50 mg. for seven days. The patient also recovered. The cortisone was very evident in this case because patients who had been treated at the same hospital died. According to the authors, this was the organism's means of defense and precluded thus enabling the specific defense system to bring about the recovery. A definitive effect of cortisone in the treatment of tetanus was evident.

Development of Low Salt Syndrome During Dehydration in Cardiac Insufficiency.—Harvald and Astrup discuss the danger of the development of secondary uremia in patients with cardiac insufficiency treated with mercurial diuretics and salt poor diet. They followed 16 patients during dehydration treatment consisting of one or two mersalyl injections (1-2 ml.) weekly in connection with a salt poor diet containing only a small amount of salt daily. Powerful dehydration therapy with salt poor diet can gradually lead to the so-called low salt syndrome. The subjective symptoms of salt depletion are fatigue, apathy, thirst, anorexia, general muscular weakness, muscular spasms, and tendency toward syncope. The syndrome is accompanied by reduced renal function and abnormally high blood urea concentration, usually also hypochloremia, and possibly hypopotassemia and hyponatremia. On the development of the low salt syndrome the mersalyl medication must be stopped at once and sodium chloride given by the mouth, whereupon the symptoms disappear. When the blood urea and serum electrolyte concentrations are returned to normal the mersalyl treatment can be resumed. The diuretic effect of mersalyl is more dependent on the serum chloride concentration than on the serum sodium concentration. It is suggested that mersalyl affects the chloride resorption in the renal tubules, not, as usually assumed, the tubular resorption of sodium.

Anemia and Sideropenia After Gastrectomy.—Wallensten's 364 cases of gastroduodenal ulcer operated on (Billroth 2) at the Serafimerlasarett consisted of 281 cases of duodenal ulcer in 201 men and 80 women, of whom 205 were under 50, and 83 cases of gastric ulcer in 58 men and 25 women, of whom 35 were under 50. On follow-up examinations with reference to postoperative anemia Vahlquist's values of 13.6 gm. per 100 cc. for men and 11.5 gm. per 100 cc. for women were taken as normal. Postoperative hypochromic anemia was found to be common after Billroth 2. Pernicious anemia did not occur. There was a high percentage of sideropenia in these anemias. The longer the time after operation, the greater was the frequency of both anemia and sideropenia. The anemia was seen oftener in women operated on before the menopause than after it. According to earlier investigations anemia is infrequent in gastric and duodenal ulcers operated on according to Billroth 1. Billroth 1 is advocated as the method of treatment for gastric ulcer and duodenal ulcer in women, but in duodenal ulcer in men Billroth 2 should continue to be the procedure, since in these cases the danger of recurrence is greater after Billroth 1. The cases should be closely followed postoperatively with regular blood control and anemia compensated by iron intravenously as oral therapy is ineffective.

Lymphosarcoma of Stomach.—From 1 to 2% of the malignant tumors of the stomach are represented by mesenchymal tumors, fully half of which are lymphosarcomas. About 600 cases of these lymphosarcomas have now been published. Recent statistics, Engberg states, show that the five year survival rate after radical operation for lymphosarcoma of the stomach is high and increasing. The importance of diagnosis is stressed. It may be extremely difficult. To date correct preoperative diagnosis has been made in only a few cases, but with the pos-

sibility of lymphosarcoma of the stomach in mind in "atypical carcinomas" diagnosis should be possible much earlier. The tumors manifest themselves at any age but occur mainly at an earlier age than carcinomas and are somewhat more frequent in men than in women. The symptoms are vague and the course is slow. In fully 50% a large palpable tumor is found or at least a definite resistance in the epigastrium is felt on the first consultation. The absence of demonstrable ascites and metastases should suggest sarcoma. In a relatively young patient in good condition with a large epigastric tumor, demonstrable roentgenologic changes in the stomach, and long history, the diagnosis of lymphosarcoma should be considered. Benzidine tests in the feces are less constantly positive and achylia is less frequent than in carcinoma. While roentgen examination is a valuable aid there are no pathognomonic signs. So far, diagnosis by means of gastroscopy has been the exception. Treatment is total or subtotal resection of the stomach and resection of omentum, most often with intensive roentgen treatment. Lymphosarcomas are exceedingly radiosensitive. Laparotomy is contraindicated only in the most advanced cases in cachectic patients. The excellent results now reported depend on intrepid radical intervention. Even advanced cases of so-called "inoperable carcinomas" call for exploratory laparotomy to rule out possible lymphosarcomas. Two cases recently treated in Randers Centralsykehus are described.

Psychosurgery for Intractable Pain.—It is emphasized that psychosurgery is definitely a last resort in cases of intractable pain. Prefrontal lobotomy, the technique most frequently used, can ameliorate pain in some cases, but rarely suppresses it definitively. Of this series of 57 patients, 43 were operated on for severe pain from neoplasms and/or metastases, 4 for cenesthopathia, 3 for sympathalgia, 2 for pain resulting from trauma to the brachial plexus, 1 for pain from a thalamic syndrome, 1 for pain from the stump of an amputation for osteomyelitis, 1 for causalgia from anesthetic leprosy, 1 for causalgia with edema following a fracture that was treated by means of a cast, and 1 for tabes with cystalgia. The authors have drawn the following conclusions. 1. Lobotomy done bilaterally in one operation, which was performed in 23 of the patients in this series, often yields good results. There are, however, serious disturbances in personality accompanying the relief of pain. There were three deaths attributable to intervention in this group. 2. Bilateral lobotomy in two stages, done in seven patients, did not yield as constant results in relieving pain. 3. Unilateral lobotomy, which was done 5 times on the right and 15 times on the left, often has a favorable result; but the effect is not so long-lasting as in the bilateral operation and it is often difficult to get the patient's family to accept another operation. The personality disorders often associated with this procedure were less severe and did not last so long as those following bilateral lobotomy. It was not possible to demonstrate a dominating analgesic effect, either homolaterally or contralaterally. 4. Excision of certain areas, or topectomy, was performed in seven cases; the results were only transitory, and the procedure was believed to have contributed to death in two aged, hypertensive patients. 5. In four of the patients in this series, lobotomy was done chemically rather than surgically. It should be done bilaterally, the authors feel, and they think it is of value for delicate patients. Studies ought to be made of this procedure's particular influence on personality. 6. It is believed that the analgesic effect caused by psychosurgery is due to its effect on the autonomic nervous system by means of a thalamohypothalamic disengagement. This would explain both the sensomotor and the psychoaffective changes that occur. After lobotomy, pain is better tolerated because the autonomic

nervous system has been brought down to a more primitive level, a level approximating that of children in whom, it is pointed out, the evolution of a cancer involves little or no pain. In three of the authors' patients, edema was reduced by psychosurgery, another fact in favor of the theory of a neurovegetative mechanism. This theory also accounts for the unusually good results obtained in the cases of sympathalgia and causalgia.

Artificial Hibernation.—The experiments on dogs made by the author and his associates have led him to propose artificial hibernation for the treatment of three conditions in man—myocardial infarction with shock, myocardial infarction without shock, and angina pectoris of coronary origin. It was found that ordinary anesthesia could not prevent the death of dogs in which the coronary arteries were ligated, but a dog in an induced state of hibernation could survive this procedure. The author proposes to induce a state of hibernation in patients with myocardial infarcts who are in shock. Both pharmacodynamic agents, such as Largactil (dimethylamino-propyl-N-chlorophenothiazine hydrochloride), Phenergan (10-[2-dimethylamino-1-propyl]phenothiazine), and meperidine (Dolosal), and ice bags placed on the axillas and the groin would be used. This treatment would be both preventive and curative; it should preferably be done at the first sign of infarction. The dangers resulting from the hypotension of shock would be obviated by the reduction of the metabolic needs of the body as a whole. Pain would be suppressed, cardiac irritability diminished, and the cardiac rhythm slowed. The technique of therapy proposed for human beings is described in detail. The administration of vitamins and heparin is included in the treatment, which is to last four days. In the case of myocardial infarction without shock, only pharmacodynamic agents are used, along with heparin and etaphylline. A small number of patients has already been treated in this manner; the procedure had the great advantage of stopping immediately intense pain that had not yielded to morphine. Two of the drugs used in intravenous infusion or intramuscularly to induce complete or partial hibernation in the patients with infarcts, Largactil and Phenergan, could also be used in small daily oral doses for the prevention of angina attacks. Their sympatholytic action could presumably moderate the apparition or accentuation of coronary sclerosis and coronary spasm. In cardiovascular surgery, artificial hibernation can perform the same services that it does in general surgery. It permits of long periods of circulatory arrest without ventricular fibrillation and the loss of cerebral electric activity that ensues is purely temporary. It would seem, therefore, that the artificial heart and lung could either be dispensed with entirely or used in conjunction with artificial hibernation with hypothermia.

Acetyl-Digitoxin in Cardiac Dysrhythmia.—Acetyl-digitoxin was administered to 120 patients with severe cardiac insufficiency. Two-thirds of these patients were over 60 years old, and three-fourths of them presented one or several serious complications—thrombosis, pulmonary infarct, pneumonia, apoplexy, or Laennec's cirrhosis. Treatment with acetyl-digitoxin brought good results, particularly in all tachycardiac forms of cardiac insufficiency. The drug also proved valuable in bradycardiac forms, but it appears that less vagotropic agents would be preferable. Dosage of acetyl-digitoxin must be separately determined for each patient; rapid or slow saturations can be effected in more or less urgent cases. The drug is well tolerated. In the series reported, 43% of the patients had excellent results, 38% good results, and 19% no improvement. Other cardiotonics also gave poor results in this last group. The properties of acetyl-digitoxin place it pharmacologically between digitoxin and the glucosides of lanatose digitalis.

Vitamin K₁ and Anticoagulant Therapy.—Synthetic vitamin K₁ (Konakion) was administered to four patients receiving Marcoumar (3[1'-phenyl-propyl]4-hydroxycoumarin) and three receiving ethyl biscoumacetate (Tromexan ethyl acetate). The good effects of the vitamin, which was given orally in doses of 10 to 12 mg., became evident in most instances six hours after its administration. In one patient receiving Marcoumar, the prothrombin time was shortened from 70 to 32 seconds in 10 hours and from 32 to 28 seconds in the next 24 hours. Twelve hours after the administration of a second 10 mg. dose of the vitamin, it was reduced to 23 seconds. Equally good effects were obtained in the other six patients. Similar results have been reported by American and English authors. They, however, had given their patients a single dose of 500 mg. of the vitamin, whereas Gagliardi never used more than from 10 to 24 mg. of it. Synthetic vitamin K₁ greatly improves the prognosis of patients receiving anticoagulants with a bishydroxycoumarin-like action, because with its administration the hemorrhagic complications secondary to this therapy can be prevented.

Cortisone Therapy in Tetanus.—Three patients with tetanus were given cortisone as supplement to antitoxin serum and penicillin. Although the authors could not judge what part the hormone played in attenuating the course of the disease, they say that it did have a favorable effect on the clinical course and brought relief to the patients by rapidly lowering the elevated temperature, reducing the intensity and number of spasms, and improving the patients' vital sense and appetite. The first patient, a 5-year-old girl, was hospitalized with a diagnosis of meningitis. After the presence of tetanus was established, she was given antitoxin serum, penicillin, and cortisone. She received the hormone first in two 50 mg. injections and later in one 50 mg. injection daily for a total dose of 1,500 mg. She recovered in about two weeks. Antitoxin serum and penicillin were given to the second patient, a 17-year-old girl, but her already severe condition was aggravated by the therapy. Cortisone was then administered in doses of 200 mg. for one day, 100 mg. for 6 days, and 50 mg. for 14 days. There was a noticeable improvement with disappearance of the spasms and recovery. The severe infection had remained undiagnosed in the third patient, a 64-year-old man. After the correct diagnosis was established, massive therapy was instituted, and, in addition to antitoxin serum and penicillin, he was given 300 mg. of cortisone for three days, 200 mg. for seven days, 100 mg. for seven days, and 50 mg. for three days. This patient also recovered. The cortisone action was particularly evident in this case because patients in similar conditions who had been treated at the same hospital without cortisone died. According to the authors, this hormone potentiates the organism's means of defense and prevents their exhaustion thus enabling the specific defense systems to intervene and bring about the recovery. A definitive evaluation of the value of cortisone in the treatment of tetanus is, however, still premature.

Dosage of acetyl-digitoxin must be separately determined for each patient; rapid or slow saturations can be effected in more or less urgent cases. The drug is well tolerated. In the series reported, 43% of the patients had excellent results, 38% good results, and 19% no improvement. Other cardiotonics also gave poor results in this last group. The properties of acetyl-digitoxin place it pharmacologically between digitoxin and the glucosides of lanatose digitalis.

BOOK REVIEWS

Injuries of the Spinal Cord. Edited by George C. Prather, M.D., F.A.C.S., and Frank H. Mayfield, M.D., F.A.C.S. Cloth. \$8.75. Pp. 396, with illustrations. Charles C Thomas, Publisher, 301-327 E. Lawrence Ave., Springfield, Ill.; Blackwell Scientific Publications, Ltd., 49 Broad St., Oxford, England; Ryerson Press, 299 Queen St., W., Toronto 2B, 1953.

This monograph is written by a group of physicians who were responsible for the care of patients with injuries to the spinal cord in United States Army general hospitals during World War II. Patients with severe injuries are encountered occasionally in civilian practice, but it is only under unusual conditions such as war that a large number of cases are available for definitive study and prolonged therapy. The monograph was written to give the student and physician all of the information necessary for the diagnosis and management of these patients. The authors are all eminent specialists in their various fields. There is a brief chapter on history followed by discussions of the management of the patient in the acute and subacute phases, the neurosurgical and urological aspects, the problems of nutrition, associated injuries, the treatment of decubitus ulcers, and the management of the patient after the acute phase, with particular emphasis on rehabilitation. The authors have relied mainly on their own clinical experience in their presentation of the subject, but a fairly extensive list of references is appended to each chapter. The material is well presented. Indications for diagnostic procedure and therapeutic measures are clearly outlined. The printing is excellent and easily read. The figures are pertinent and clearly reproduced. There is an adequate index. The book should be of great value to students and physicians who are responsible for the care of these patients, particularly neurologists, neurosurgeons, orthopedists, and physiatrists.

The Radiology of Bones and Joints: An Introduction to the Study of Tumours and Other Diseases of Bone. By James F. Brailsford, M.D., Ph.D., F.R.C.P., Consulting Radiologist to Queen Elizabeth Hospital, Birmingham, England. Fifth edition. Cloth. \$19. Pp. 875, with over 725 illustrations. Williams & Wilkins Company, Mount Royal and Guilford Aves., Baltimore 2, 1953.

This book is now in the fifth edition and is widely used by many radiologists in this country. Over the years the clinicians, the orthopedists, and the radiologists have had great difficulty in interpreting bone and joint disease as portrayed on the roentgenogram. With experience it is possible to make presumptive roentgenologic diagnoses that will include several conditions; for instance, the roentgenographic evidence of osteomyelitis may simulate the findings of a Ewing tumor. Often it is impossible to differentiate between the two by the roentgenologic examination alone, and it is only after correlating the roentgenologic with all the other findings, including the pathological findings, that a correct diagnosis is made and proper treatment is instituted. The author, because of his vast experience, has collected roentgenograms of many conditions, and a short discussion of these conditions is included in the text.

It is difficult to reconcile the following statement of the author with good medical practice: "The author acknowledges the great debt that we owe to clinicians and pathologists. . . . By correlation of the clinical with the histopathological and with radiography we have learned a great deal about the significance of radiographic appearances. . . . Why . . . submit the tuberculous and multitudinous other conditions to biopsy with all its risks in an attempt to secure 'confirmation'? The summations of reports from many sources on relatively limited knowledge do not add up to accuracy. The superficial resemblances of clinical, microscopical and radiological features of widely different lesions do not permit a sound teaching by 'atlas' methods." There are bone conditions in which a correct

diagnosis can be made from the roentgenogram, but there are many other important lesions in which every possible aid is needed, including microscopic studies of excised tissues.

The author's descriptions are largely radiological; little consideration is given to the lesions producing the radiological appearances, and there are certain subjects, such as meningiomas, that receive only meager comment. On the other hand, this book includes a wealth of information, which should be helpful to the radiologist. The format of the book is good. The type is easy to read, but the illustrations unfortunately are mostly positive roentgenograms. The author is to be congratulated on the index. It is refreshing to be able to turn to an index of a medical book and find the subject sought.

What You Should Know About Mental Illness. By Orin Ross Yost, M.D., Medical Director, Edgewood Sanitarium Foundation, Orangeburg, S. C. With foreword by Nolan D. C. Lewis, M.D., introduction by Leland E. Hinsie, M.D., and note by Norman Vincent Peale, D.D. Cloth. \$3.50. Pp. 165. Exposition Press Inc., 386 Fourth Ave., New York 16, 1953.

Dr. Yost has written a most readable little book. Although he is a prominent figure in the field of psychiatry, he has by no means written this book specifically for psychiatric consumption. In considering the Baconian tripartite division of books, "some to be tasted, some to be chewed, and some few to be swallowed and digested," this present work is neither superficial enough to be accorded the first nor profound enough for the last. This is neither a reference book nor a textbook or manual but an honest plea for a better understanding of mental illness, coupled with suggestions for a community-minded drive toward better mental health. It suffers by comparison with Halliday's striking analyses but has perhaps the merit of "getting through" to a larger cross section of the interested reading public. Dr. Yost says nothing that the psychiatrist and psychologist does not already know and has not already said, but his approach is more in accord with the popularizing trend in scientific literature. The scientist may be mildly startled by such a folksy script writer technique as is seen at the beginning of chapter 1: "Our plane was speeding westward across the continent. Only a few short hours before, we had left the airport in New York, and we were already a short distance beyond Chicago, the Windy City. Glancing idly at a newspaper which a fellow passenger had offered to share with me, my eye fell on a headline that arrested my attention: 3,548,000 Babies Born Last Year. It was an official figure from the Bureau of the Census. I saw in my mind's eye those squirming, laughing, crying, cooing infants—a cross section of the America of tomorrow. Among them would be all sorts of babies—yellow, red, white, black; long babies, short babies, chubby and thin ones, all kinds and conditions of babies—our country's most precious resource."

Fortunately his mind's eye is rapidly cleared of the "chubby and thin ones" and he goes on to a clear and lucid exposition of mental function from topographical, dynamic, and economical viewpoints, with a wealth of apt illustration and example. He pays compliment to the roles of various important socioenvironmental factors—the mother, the teacher, and the community. This is followed by a necessarily concise but accurate discussion of psychopathology in terms that enlighten but do not in the process disturb. It is difficult to see why the more technical procedures of psychotherapy and psychosurgery are interpolated between psychopathology and discussion of such conditions as alcoholism, drug addiction, epilepsy, and suicide, but perhaps Dr. Yost was using the social impact of such phenomena to lead up to his final chapters on social responsibility and the interrelationship between psychiatry and religion. This book should do much to stimulate the desire to approach the literally awful problem of mental illness on the grand scale that is so urgently required. The suggestions that he makes are valuable and positive, and his book renders a definite service to community and national needs.

Sexual Behavior in the Human Female. By Alfred C. Kinsey, Wardell B. Pomeroy, Clyde E. Martin, and Paul H. Gebhard, Research Associates, Institute for Sex Research, Indiana University, Bloomington. Cloth, \$8. Pp. 842, with 155 illustrations. W. B. Saunders Company, 218 W. Washington Sq., Philadelphia 5; W. B. Saunders Company, Ltd., 7 Grape St., Shaftesbury Ave., London, W.C.2, 1953.

There are few works published in the last decade that have excited as much comment and argument as "Sexual Behavior in the Human Female." Because of this controversy THE JOURNAL ignored its usual practice of submitting a book for review to one person; in this instance two persons, both widely known in their fields, have been asked for reviews.—ED.

A great deal has been written and said about the Kinsey reports on the sexual behavior of the human male and female. For some reason the title of this book bears the earmark of a neologistic twist, for it reads: "Sexual Behavior in the Human Female." Attention is called to this not because a carping thrust at Kinsey and his collaborators is intended but rather to point up a certain aspect of Kinsey's thinking that interferes with the clarity of his scientific attitude. There is no doubt that Kinsey's general approach is scientific. There is no doubt that his approach suffers from a number of defects and that it also enjoys, in many respects, the credit of validity of any serious scientific undertaking. What seems lacking in Kinsey's approach, however, is a true awareness of the fact that we are dealing with a complex psychobiological phenomenon. Behavior in the human female is not a phenomenon but a semantic artifact. Behavior is a part of the human being, and it is the manifestation of a complexity called a personality. Neither biology nor medical psychology would place objective behavior within a person.

If Kinsey had deliberately and overtly left out of consideration the psychological aspects of the problem on which he worked, there would be reason for regretting such an omission, but one would not quarrel with the omission. It is the privilege of the research worker to limit his field of investigation in any manner he wishes. The trouble is that Kinsey does not leave out human psychology but deals with it almost in the manner of a nonscientific layman who tries to give authoritative voice to his prejudices. This is a defect of serious importance.

Kinsey thus states almost glibly: "Freudian hypotheses of psychosexual development proceeding, as a rule, from narcissistic (masturbatory) interests and activities to interests in other individuals whose bodies are similar (the homosexual interests), and finally to interests in individuals who are physically different (the heterosexual interests), are not substantiated by the preadolescent or adolescent histories of either the females or the males in the sample" (page 109). The above is not an accurate presentation of the Freudian hypotheses, nor does it include the central points of Freudian considerations—the evolution of the love affects that accompanies the evolution of psychosexual development, an evolution that culminates normally in object love and the striving toward parenthood. To omit love and the inner aspiration to become a parent is to omit that which makes the human (male or female) human. Leave love out of consideration and you have no sexual behavior, but only a manifestation of the physiological reaction of the sexual organs and their adnexa. Modern biology has no more right than modern medicine to exclude the human elements from the human being—for the totality of the psychobiological unit that is man is not overlooked today either by the practicing physician or by the medicopsychological research worker.

Then, too, one wonders how it happens that Kinsey feels justified in stating that the above-mentioned Freudian hypotheses "are not substantiated by the preadolescent or adolescent histories of either the females or the males in the sample." How did Kinsey go about verifying these hypotheses about the evolution of the human personality, which lies primarily in the sphere of the unconscious? It is as if one observed carefully a flight of birds and then stated that Newton's formulation about the laws of gravity is not substantiated in the sample of flying ducks.

There seems to be a lack of understanding of such psychosexual phenomena as "vaginal orgasm"—Kinsey shows the common tendency to look for specific innervations, which is not too hopeful an attitude from the standpoint of scientific understanding of the phenomenon. After all, in dealing with sexual issues we are considering a supercharged human instinct that is responsible for the greatest artistic inspirations and most heinous

crimes in human history. And yet Kinsey looks upon it all with the simple eye of an old-fashioned behaviorist making rather trite and general references to learning and conditioning.

He seems to encourage masturbation (page 263) and overestimate the physiological, sensual orgasm without considering the psychological factors that might inhibit the healthiest neuromuscular apparatus and leave a sense of affective vacuum even after the most intense physiological orgasm. Clinically we may observe this in patients with neuroses and involution psychoses (particularly in women). The whole field of clinical considerations seems to escape Kinsey, and his apparent biases lead him to such striking statements as this, for instance: "It should, however, be emphasized again that most of the husbands who accepted or encouraged their wives' extra-marital activity had done so in an honest attempt to give them the opportunity for additional sexual satisfaction" (page 435). Of course the above statement is both sweeping and inconclusive, for it omits the consideration of human affects and overlooks the simple clinical fact that the alleged good will of the singularly permissive husbands in question is in itself a sign of a serious clinical condition with which the practicing psychiatrist is not unacquainted.

It is difficult to rid one's self of the impression that from the clinical, psychobiological point of view Kinsey's latest book is not very scientific and that he falls frequently into the same formalistic, pseudoscientific trap that characterized the classical Greeks and the Arabs like Avicenna, who considered love an illness because it produced a flushed face and an accelerated pulse. When Kinsey speaks of some "physiological effects," his approach is almost that of the ancients who disregarded love and overestimated the orgasm as an end in itself (page 171 or 166).

One cannot but admire the perseverance and tenacity with which Kinsey sticks to his work, but from the medicopsychological point of view he does dehumanize both the human male and the female. And he does this despite the best perspectives offered by modern medical psychology—all this even if we leave entirely out of consideration the question of traditional morality and sex.

(Second review)

The present volume constitutes the second progress report on the study of human sex behavior that has been under way for 15 years at the University of Indiana. Dr. Kinsey and his associates have had charge of this project, which has been supported by the Rockefeller Foundation through the Committee for Research on Problems of Sex of the National Research Council. It has been a fact-finding survey in an attempt to discover what people do sexually, what factors account for their patterns of sexual behavior, how their sexual experiences have affected their lives, and what social implications there may be in each type of behavior.

The data in this volume are based on personal interviews with 5,940 white women from a total of almost 8,000 women who were interviewed. Much criticism has been directed against the selection of the persons who comprise this study, for they are not necessarily representative of our female population. The investigators acknowledge this defect in their material and note that a better sampling was not possible because they had to make use of those volunteers who presented themselves. They obtained detailed information about the lives of the women who were interviewed and their various sex practices. The questions concerned masturbation; nocturnal sex dreams; premarital petting; premarital, marital, and extramarital coitus; and homosexual responses. All of these forms of sexual gratification were brought together to provide a pattern of the total sexual outlet of the groups of women who were studied. The data are presented in a series of tables at the end of each chapter and illustrated by many simple graphs. The historical, social, moral, religious, and emotional implications are discussed fully. There are extensive references to the old and current literature, which are presented in footnotes throughout the text.

The last five chapters are devoted to the anatomy, physiology, and the neural mechanism of the sexual response and orgasm. The psychological and hormonal factors that may influence the sexual act are discussed. The male and the female are compared in these pages, and the authors suggest that there are no great differences between the sexes except that psychological factors probably play a more important role in men than in women. A comprehensive bibliography is included.

This report is a detailed, careful, scientific analysis of a fairly large sampling of our feminine population. Together with the report on the human male, many pertinent facets of human sexual behavior are presented. Although the groups investigated may not be representative of our population and the implications may not be valid for any one person or group of persons, the data are the best available at present. This book does not qualify as a sensational sex thriller but does represent a scientific report of a study still in progress, which is being diligently pursued by a group of experts well qualified to carry on this project. This book and its companion volume on the male should be read by physicians, educators, sociologists, and all others who are seriously interested in human sexual behavior.

Handbuch der Inneren Medizin. Begründet von L. Mohr und R. Staehelin. Herausgegeben von G. v. Bergmann, W. Frey, und H. Schwiégk. Fünfter Band, Teile 1-3: Neurologie. Redigiert von R. Jung. Teil 1, bearbeitet von R. Brun, et al. Teil 2, bearbeitet von P. E. Becker, et al. Teil 3, bearbeitet von E. Bay, et al. Fourth edition. Cloth. 656 marks; subscription price, 524.80 marks. Pp. 1543, with 591 illustrations; 966, with 286 illustrations; 1531, with 388 illustrations. Springer-Verlag, Reichpietschauer 20, (1) Berlin W. 35 (West-Berlin); Neuenheimer Landstrasse 24, Heidelberg; Göttingen, 1953.

This section on neurology of the "Handbook of Internal Medicine" is within the great tradition of the German scientific handbooks. Although less extensive than Foerster's famous "Handbuch der Neurologie," it devotes about 3,000 pages to a discussion of clinical neurology and to its anatomic and physiological foundations. About 25 authors share in this work, which has been carefully edited by R. Jung. Each contribution is provided with an extensive bibliography listing monographs and special papers and with numerous figures. The quantity of these illustrations is indicated by the fact that the chapter on arteriography has 49 figures. In general, the whole field has been reviewed objectively, without eliminating the special flavor of individual articles that is based on the particular experience of the writer. The Anglo-American literature is extensively utilized. There is a detailed author and subject index, and the printing and binding are excellent. The work is highly recommended as an authoritative review of theoretical and clinical neurology.

Volume 1 contains essays on the general physiology of the nervous system; the general anatomy, physiology, and pathology of peripheral nerves and symptoms resulting from their disorders; the spinal cord; the autonomic nervous system; and the brain. The second volume describes neurological methods (clinical and laboratory); medical and surgical therapy; and the diseases of peripheral nerves, spinal cord, autonomic nervous system, and muscles. This volume also includes a special article on multiple sclerosis. The third volume deals with circulatory disturbances and inflammatory diseases of the brain; syphilis, trauma, and tumors; diseases of the brain stem, extrapyramidal system, and cerebellum; epilepsy and related conditions; and symptomatic psychoses and neuroses.

The Symptoms and Treatment of Acute Poisoning. By G. H. W. Lucas, Professor of Pharmacology, University of Toronto, Toronto, Ontario. Cloth. \$4. Pp. 308. The Macmillan Company, 60 Fifth Ave., New York 11, 1953.

This book was written to provide practicing physicians with a ready reference for treating patients who have been poisoned. The subjects considered include supplies and apparatus, emetics and gastric lavage, poisonings in children, collections and preservation of samples for analysis, useful drugs and preparations, and cases of poisoning. A most noteworthy addition is the chapter on poisonings in children, since this always presents a special problem to the physician. In addition a table of approximate equivalents, domestic measures, etc., and a table of fatal doses are included. The book is complete as to the number of toxicologic agents discussed. The index is easy to consult. Trade names are used along with the generic names, and in the index the trade names have been placed in italics together with an abbreviation for the name of the manufacturer. The book can also be used as a practical handbook on the symptoms and treatment of acute poisoning by dentists, nurses, and pharmacists. This is a useful addition to the literature of toxicology.

Side Effects of Drugs. By L. Meyler. Translated by Ph. Vuijsje and W. Mulhall Corbet. Cloth. \$5.50. Pp. 268. Elsevier Press, Inc., 402 Lovett Blvd., Houston 6; 155 E. 82nd St., New York 28; 118 Spuistraat, Amsterdam C, Netherlands, 1952.

This reference book lists the side-effects that may occur after the therapeutic administration of drugs. It provides the practicing physician with a handy and somewhat extensive guide to determine whether unexpected symptoms are the result of the disease or are actually the side-effects of the drug. The book includes most compounds in common use. The drugs are classified according to their therapeutic properties. Two special chapters are devoted to metals and metalloids and one to serums and vaccines. The book is well documented and contains an extensive bibliography at the end of each chapter. The index is well arranged and complete. The author has included very little critical evaluation of the side-effects discussed. That the incidence of occurrence of the side-effects is not indicated is another drawback. In this age of antibiotics and chemotherapy, however, this handy reference should prove of unestimable value.

Influenza and Other Virus Infections of the Respiratory Tract. By C. H. Stuart-Harris, M.D., F.R.C.P., Professor of Medicine, University of Sheffield, Sheffield, England. With foreword by C. H. Andrewes, M.D., F.R.C.P., F.R.S., Deputy Director, National Institute for Medical Research. Cloth. \$6. Pp. 235, with 98 illustrations. (Williams & Wilkins Company, Mount Royal and Guilford Aves., Baltimore 2); Edward Arnold & Co., 41-43 Maddox St., London, W.1, 1953.

Acute viral infections of the respiratory tract are a greater problem than ever in clinical practice because of the success of antibiotics and sulfonamides in overcoming bacterial infections. In this book a distinguished English authority successfully differentiates what is known about influenza, virus pneumonia, and other common respiratory diseases from what is still nebulous and vague. Influenza receives the most attention, both because of its importance as a potential killer and because of knowledge already gained by concerted clinical, epidemiological, and laboratory investigations. In addition, there are several informative and instructive chapters on the common cold, febrile catarrh, atypical pneumonia, psittacosis and ornithosis, Q fever, and laboratory diagnosis. This book contains much valuable information and is highly recommended to specialists and general practitioners alike.

Advances in Virus Research. Volume I. Edited by Kenneth M. Smith and Max A. Lauffer. Cloth. \$8. Pp. 362, with illustrations. Academic Press, Inc., 125 E. 23rd St., New York 10, 1953.

The effective dissemination of the results of virus research has suffered greatly through the lack of journals primarily devoted to this field. This is particularly true with fundamental investigations of the nature and immediate characters of the viruses themselves, the reports of which are scattered widely in publications not often consulted except by specialists in the basic sciences. In this volume an attempt is made to present each year timely reviews of progress in the study of those properties of viruses that establish their place in the biological, physical, and chemical worlds. The first volume contains an absorbing account of the insect viruses effectively illustrated by electron micrography by G. H. Bergold. A fertile field of contemporary research is that of virus multiplication. The work of this character on bacteriophages is reviewed by Epstein, and that with the influenza virus is considered exhaustively by Henle. The general problems and results of virus purification are discussed by Sharp. The properties and functions of nucleic acids in viruses are described by Markam. The phenomenon of interference between viruses resulting in protection against or suppression of infection of one by the other is reviewed by Bennett, and the transmission of plant viruses by insect vectors, the leaf hoppers, is recounted by Black. A comprehensive account of the properties of the poliomyelitis virus relative to types, culture, growth, immunologic properties, and gamma globulin prophylaxis is given by Melnick. The reviews are excellent, and the series of publications within a few years should provide a highly concentrated source of the principal findings in the nature and properties of viruses.

QUERIES AND MINOR NOTES

DISCOID LUPUS ERYTHEMATOSUS

TO THE EDITOR:—A married woman, aged 37, has had discoid lupus erythematosus for 15 years. She received treatment at several clinics, all to no avail. Quinacrine (Atabrine) therapy was begun on April 10, 1953, and the dose was increased from 50 to 150 mg. daily. All lesions blanched and the subjective symptoms, such as stinging and burning, disappeared. There have been occasional short attacks of nausea, vomiting, and diarrhea. She is now taking a maintenance dose of 75 mg. of quinacrine daily, and, while there has been a moderate return of redness to the lesions, there has been neither burning nor induration. How long may this maintenance dose be given?

George M. Kest, M.D., Port Huron, Mich.

This inquiry was referred to two consultants, whose respective replies follow.—ED.

ANSWER.—In general, in an attempt to avoid toxic reactions in quinacrine (Atabrine) therapy of discoid lupus erythematosus, a rest period is given sometime during the course of treatment. The weight loss, diarrhea, and nausea in this patient are reactions to quinacrine, although not serious ones. It is recommended that the maintenance therapy be discontinued for three to four weeks if the skin lesions are doing well. The blood cell counts and urinalyses should be done even during this rest period, for sometimes the toxic reactions may be delayed. Chloroquine diphosphate is less toxic than quinacrine and may be substituted for quinacrine at the end of this rest period in a dosage of 250 mg. twice a day or even only once a day for a period of several months. If the skin lesion is under good control, then all therapy may be stopped unless a flare-up occurs. If the patient's lesions usually flare-up in spring, then a preventive routine of 250 mg. of chloroquine diphosphate may be started early in March. If an active flare-up occurs, 250 mg. four times a day may be given. Routine blood cell counts and urinalyses should be done also in chloroquine diphosphate therapy.

ANSWER.—The drug may be given as long as necessary if the patient is observed at frequent intervals for signs of intolerance. Perhaps it would be well to change to chloroquine which is less toxic than quinacrine, beginning with 0.25 gm. three times daily for a while then reducing to an effective maintenance dose.

HIRSUTISM AT THE CLIMACTERIC

TO THE EDITOR:—I have seen two cases of lanugo-type hair on the faces of two women, aged 40. One apparently had a short period of functional bleeding and the other was approaching the climacteric. Could you suggest a differential diagnosis?

M.D., Maine.

This inquiry was referred to two consultants, whose respective replies follow.—ED.

ANSWER.—It has long been thought, and with good evidence, that the pilary system is controlled by the endocrine glands such as the gonads, thyroid, anterior pituitary, and adrenal cortex. It is not surprising therefore that some hirsutism should appear at the time of the climacteric. Idiopathic hirsutism of a permanent character has also been observed after puberty and pregnancy as a genetic characteristic and after diseases such as mumps, encephalitis, neuritis, and multiple sclerosis. Certain drugs such as diphenylhydantoin (Dilantin)

and testosterone may produce transient hirsutism. Since there was no evidence of any of these factors nor of endocrine gland tumors in either of these two cases, it may be assumed that the hairs are associated with the menopause.

ANSWER.—It is not uncommon for facial hirsutism to develop in women approaching the climacteric. The mechanism of this excessive hair growth is not very well understood. Diminution of estrogen secretion by the ovaries may be responsible for it; however, the administration of estrogen does not influence the hair growth to any marked degree. Estrogen-containing facial creams have been used with some slight success. Apparently, the androgens secreted by the adrenal cortex control hair growth, and it is difficult to influence the secretion of these androgens. In a differential diagnosis of the condition, the investigation should center around the function of the adrenal cortex, and a 17-ketosteroid determination would reveal whether there is excessive androgen secretion. Not uncommonly a slight or even moderate increase in excretion of 17-ketosteroids is found in this condition. Only when a great excess is found should procedures aimed at removing portions of the adrenal cortex be considered. Another theory regarding the development of hair growth in women implicates the theca cells of the ovary, which elaborate an androgen. This, however, is speculative at the present time, and it is only in cases of arrhenoblastoma that ovarian tissue is known to elaborate androgens.

NUMBNESS OF HANDS IN PREGNANCY

TO THE EDITOR:—I frequently encounter pregnant women who complain of numbness and tingling of the hands. Others complain of a painful stiffness of the fingers, especially in the morning, that improves with use during the day. At times there is a slight swelling of the hands and temperature changes are noted. These patients all have had adequate calcium and vitamin intake, and the sodium and water balance has not been deemed a factor. All symptoms have spontaneously disappeared during the puerperium. What is the cause and treatment of this condition?

Fred S. Taber, M.D., New Brunswick, N. J.

This inquiry was referred to two consultants, whose respective replies follow.—ED.

ANSWER.—Stiffness of the joints and slight swelling of the hands are not unusual in pregnancy and during the premenstrual period. They are due to the sodium retention that attends these states, and accordingly they ordinarily respond to sodium restriction or ammonium chloride. There is no good explanation for the more troublesome paresthesias of the hands that are occasionally seen during pregnancy, and these usually follow the distribution of the ulnar nerve. Large doses of vitamins, especially the vitamin B complex, have been given without notable effect. Salt is restricted and ammonium chloride given (often with indifferent effect) on the possibility that edema at the nerve roots may be the cause. The patient who complains of continuous burning, aching pain that precludes the use of the hands should be suspected of having a serious underlying vascular or neurological disturbance and should be investigated with this in mind. Such symptoms are not among the changes of normal pregnancy.

ANSWER.—Numbness and tingling of the hands during pregnancy are forms of neuritis, the exact cause of which is not known. The condition disappears shortly after delivery. In many cases no treatment is necessary, but moist or dry heat, salicylates, codeine, and niacin may be helpful. The treatment of this form of neuritis is identical with that in nonpregnant patients.

The answers here published have been prepared by competent authorities. They do not, however, represent the opinions of any official bodies unless specifically so stated in the reply. Anonymous communications and queries on postal cards cannot be answered. Every letter must contain the writer's name and address, but these will be omitted on request.

POLIOMYELITIS AT A SUMMER CAMP

TO THE EDITOR:—*I am chairman of the medical committee of a summer camp for children. The camp consists of a common dining room and a series of bunks. In the event one of the campers contracts poliomyelitis, should all the children be quarantined or only those who resided in the same tent, the ill camper? Should any campers be allowed to return home? When should other children be allowed to come in as new campers? What period of time should be allowed later for adults to come to camp as campers?*

M.D., Ohio.

ANSWER.—The child stricken with poliomyelitis may be removed to a hospital with the consent of the proper health authorities. All other children should be confined to the camp for two weeks. There should be daily medical inspection, and, if any evidence of illness develops, the patient should be isolated. New children should not be accepted at the camp. Adults at the camp should be advised to remain. It is generally believed the danger of poliomyelitis is not diminished by leaving a camp where the disease has occurred. Local health regulations may interfere with children returning to their homes. No new campers should be admitted until at least two weeks have elapsed since the last case of poliomyelitis developed. It would be advisable to allow a period of one week to elapse after all children had left the camp before admitting adults. During that time a thorough sanitary inspection should be made of the premises. Food supplies, water, milk, and insects should receive consideration. The foregoing advice is based largely on Recommendations of the Illinois Department of Public Health issued in June, 1953.

CHRONIC ULCERATIVE COLITIS

TO THE EDITOR:—*A 19-year-old girl has had chronic ulcerative colitis for several years. Eight months ago she was operated on for an anal fistula. Since the operation, there has been practically no healing in the perineal wound despite adequate drainage and no connection with the anal canal or rectum. Suggestions of means to promote wound healing in this case will be appreciated.*

M.D., New York.

ANSWER.—The fistulous tract originally must have been connected with the lower bowel that was the site of chronic ulcerative colitis. Operative repair often involves the failure of the wound to heal because of infected material constantly lavaging the anal area and because of impaired vitality of the tissue. Clinical remission of chronic ulcerative colitis does not necessarily mean cessation of the pathological process in the colon. This may be determined by mucosal aspiration wet smear, using a heavy bore capillary tube inserted through the sigmoidoscope. A purulent cytological material in the mucosal exudate is indicative of active intramural infection. Cutting into or through such an infected area involves the hazard of poor healing, since drainage is not merely of the former fistulous tract but of the colon itself. In some instances, fecal matter may be seen in the wound because of a persistent opening in the rectum or anal canal. Operative interference should be avoided, if at all possible, for perianal conditions complicating chronic ulcerative colitis. Ischiorectal abscess is infrequent but usually must be treated surgically.

The following treatment is suggested for this patient: (1) good supportive therapy, including a high caloric, high protein diet; (2) administration of 250 to 500 mg. of ascorbic acid three times a day; (3) microcrystalline sulfathiazole powder sprinkled into the wound once or twice daily after it has been cleaned with 50% hydrogen peroxide; and (4) active immunization against the flora recovered from the wound, usually coli and enterococcus organisms. If these measures fail after 10 weeks, a short circuiting of the fecal stream (ileostomy) usually has to be done. After a second 10 week period, failure to heal may necessitate a total colectomy. Ileostomy or subtotal or total colectomy should not be undertaken lightly; they are by no means absolute solutions in chronic ulcerative colitis. On the other hand, a number of patients, such as the girl described in the query, have improved after local administration of microcrystalline sulfathiazole and conservative supportive therapy.

SMALL TUMOR NEAR HYOID BONE

TO THE EDITOR:—*A 50-year-old man suddenly discovered a small tumor in the region of the hyoid bone a bit to the right. It is about 1 in. in diameter and hard, but is asymptomatic. The diagnosis is probably a thyroglossal cyst. Do you advise removal of the cyst? What symptoms and signs could develop?*

M.D., Rhode Island.

ANSWER.—The most likely diagnosis of a round midline or near midline lesion at the level of the hyoid bone is thyroglossal cyst. It may appear at any age but usually appears in patients younger than 50. The commonest complication of thyroglossal cyst is obstruction. The mass could be an adenoma of the thyroglossal tract or even a carcinoma. There are lymph nodes in this vicinity, and it could be metastatic from a primary tumor in the thyroid below. It is quite unlikely that the roentgenogram will reveal anything significant. Since its diagnosis is uncertain, the removal of the tumor should be advised.

HAND-SCHÜLLER-CHRISTIAN DISEASE

TO THE EDITOR:—*A girl with Hand-Schüller-Christian disease died at age 4 after about three years of illness. The two healthy siblings, aged 8 and 10. The parents and other child but are afraid it might be affected. Is Hand-Schüller-Christian disease hereditary?*

Hubert W. Coleman, M.D., Avon Park, Fla.

ANSWER.—There is no evidence that lipid histiocytosis of cholesterol type (Hand-Schüller-Christian disease) is hereditary. The odds of another child being affected are so small that they do not represent an appreciable risk.

GLUCOSE SOLUTION INTRAMUSCULARLY

TO THE EDITOR:—*I would like to comment on the answer to the query on the administration of glucose solutions intramuscularly on page 100 of THE JOURNAL, Jan. 2, 1954. While sloughing will not occur if 5 or 10% glucose solutions are given intramuscularly, a temporary shift of electrolytes and some fluid into the area of injection will occur. Because of the resulting lowered electrolyte concentration in the extracellular compartment, a further transfer of water to the intracellular phase will occur. These shifts result in a depletion of the plasma and interstitial fluid that may lead to serious consequences.*

It has been shown that hypotension and oliguria may occur as a result of the decrease in the plasma volume (10 to 30%) that follows hypodermoclysis of 2,000 ml. of a 5% glucose solution in distilled water. Therefore, I feel it especially undesirable and dangerous to give glucose in water in amounts up to 80 ml. per kilogram of body weight, particularly when the patient is dehydrated or if hyaluronidase is employed. Since a considerable decrease in the plasma volume has been noted after 35 to 40 ml. of glucose in water has been given per kilogram of body weight by hypodermoclysis to normal patients, it would seem unwise to administer electrolyte-free fluids to dehydrated patients by this method. While hyaluronidase causes the fluid to spread, or diffuse, throughout a larger area, relieving pain and causing a more rapid absorption, it also accelerates the shift of electrolytes. Thus, although the undesirable shift of fluid that leads to a diminution in the plasma volume is of shorter duration, its effect is more profound when hyaluronidase is employed. For a better understanding of the dangers of administering electrolyte-poor fluids by hypodermoclysis, the following references should be consulted (*Surgery* 52:305, 1952; *Surgical Forum: Proceedings of the Forum Sessions of the 37th Clinical Congress of the American College of Surgeons*, 1952, Philadelphia, W. B. Saunders Company, 1952, pp. 559-564; *J. A. M. A.* 150:942 [Nov. 1] 1952 and *J. A. M. A.* 151:644 [Feb. 21] 1953).
